

Merritt's Neurology 10th Edition (June 2000): by H. Houston Textbook of Neurology Merritt (Editor), Lewis P. Rowland (Editor), Randy Rowland By Lippincott Williams & Wilkins Publishers

By OkDoKeY

Merritt's Neurology

CONTENTS

[Contributing Authors](#)

[Preface](#)

[Abbreviations](#)

SECTION I. SYMPTOMS OF NEUROLOGIC DISORDERS

[Chapter 1. Delirium and Dementia](#)
Scott A. Small and Richard Mayeux

[Chapter 2. Aphasia, Apraxia, and Agnosia](#)
J. P. Mohr

[Chapter 3. Syncope and Seizure](#)
Timothy A. Pedley and Dewey K. Ziegler

[Chapter 4. Coma](#)
John C.M. Brust

[Chapter 5. Diagnosis of Pain and Paresthesias](#)
Lewis P. Rowland

[Chapter 6. Dizziness and Hearing Loss](#)
Jack J. Wazen

[Chapter 7. Impaired Vision](#)
Myles M. Behrens

[Chapter 8. Headache](#)
Neil H. Raskin

[Chapter 9. Involuntary Movements](#)
Stanley Fahn

[Chapter 10. Syndromes Caused by Weak Muscles](#)
Lewis P. Rowland

[Chapter 11. Gait Disorders](#)
Sid Gilman

[Chapter 12. Signs and Symptoms in Neurologic Diagnosis](#)
Lewis P. Rowland

SECTION II. HOW TO SELECT DIAGNOSTIC TESTS

[Chapter 13. Computed Tomography and Magnetic Resonance Imaging](#)
Robert DeLaPaz and Stephen Chan

[Chapter 14. Electroencephalography and Evoked Potentials](#)
Ronald G. Emerson, Thaddeus S. Walczak, and Timothy A. Pedley

[Chapter 15. Electromyography and Nerve Conduction Studies in Neuromuscular Disease](#)
Dale J. Lange and Werner Trojaborg

[Chapter 16. Neurovascular Imaging](#)
J. P. Mohr and Robert DeLaPaz

[Chapter 17. Lumbar Puncture and Cerebrospinal Fluid Examination](#)
Robert A. Fishman

[Chapter 18. Muscle and Nerve Biopsy](#)
Arthur P. Hays

[Chapter 19. Neuropsychologic Evaluation](#)
Yaakov Stern

[Chapter 20. DNA Diagnosis](#)
Lewis P. Rowland

SECTION III. INFECTIONS OF THE NERVOUS SYSTEM

[Chapter 21. Bacterial Infections](#)
James R. Miller and Burk Jubelt

[Chapter 22. Focal Infections](#)
Gary L. Bernardini

[Chapter 23. Viral Infections](#)
Burk Jubelt and James R. Miller

[Chapter 24. Acquired Immunodeficiency Syndrome](#)
Carolyn Barley Britton

[Chapter 25. Fungal and Yeast Infections](#)
Leon D. Prockop

[Chapter 26. Neurosarcoidosis](#)
John C.M. Brust

[Chapter 27. Spirochete Infections: Neurosyphilis](#)
Lewis P. Rowland and Leonidas Stefanis

[Chapter 28. Spirochete Infections: Leptospirosis](#)
James R. Miller

[Chapter 29. Spirochete Infections: Lyme Disease](#)
James R. Miller

[Chapter 30. Parasitic Infections](#)
Burk Jubelt and James R. Miller

[Chapter 31. Bacterial Toxins](#)
James R. Miller

[Chapter 32. Reye Syndrome](#)

Darryl C. De Vivo

[Chapter 33. Prion Diseases](#)
Burk Jubelt

[Chapter 34. Whipple Disease](#)
Elan D Louis

SECTION IV. VASCULAR DISEASES

[Chapter 35. Pathogenesis, Classification, and Epidemiology of Cerebrovascular Disease](#)
Ralph L. Sacco

[Chapter 36. Examination of the Patient with Cerebrovascular Disease](#)
Randolph S. Marshall

[Chapter 37. Transient Ischemic Attack](#)
John C.M. Brust

[Chapter 38. Cerebral Infarction](#)
John C.M. Brust

[Chapter 39. Cerebral and Cerebellar Hemorrhage](#)
J. P. Mohr and Christian Stapf

[Chapter 40. Genetics of Stroke](#)
Alexander Halim and Ralph L. Sacco

[Chapter 41. Other Cerebrovascular Syndromes](#)
Frank M. Yatsu

[Chapter 42. Differential Diagnosis of Stroke](#)
Mitchell S.V. Elkind and J.P. Mohr

[Chapter 43. Stroke in Children](#)
Arnold P. Gold and Abba L. Cargan

[Chapter 44. Treatment and Prevention of Stroke](#)
Frank M. Yatsu

[Chapter 45. Subarachnoid Hemorrhage](#)
Stephan A. Mayer, Gary L. Bernardini, John C.M. Brust, and Robert A. Solomon

[Chapter 46. Cerebral Veins and Sinuses](#)
Robert A. Fishman

[Chapter 47. Vascular Disease of the Spinal Cord](#)
Leon A. Weisberg

SECTION V. DISORDERS OF CEREBROSPINAL AND BRAIN FLUIDS

[Chapter 48. Hydrocephalus](#)
Leon D. Prockop

[Chapter 49. Brain Edema and Disorders of Intracranial Pressure](#)
Robert A. Fishman

[Chapter 50. Superficial Siderosis of the Central Nervous System](#)
Robert A. Fishman

[Chapter 51. Hyperosmolar Hyperglycemic Nonketotic Syndrome](#)
Leon D. Prockop and Stephan A. Mayer

SECTION VI. TUMORS

[Chapter 52. General Considerations](#)
Casilda M. Balmaceda

[Chapter 53. Tumors of the Skull And Cranial Nerves](#)
Jeffrey N. Bruce, Casilda M. Balmaceda, and Michael R. Fetell

[Chapter 54. Tumors of the Meninges](#)
Casilda M. Balmaceda, Michael B. Sisti, and Jeffrey N. Bruce

[Chapter 55. Gliomas](#)
Casilda M. Balmaceda and Robert L. Fine

[Chapter 56. Lymphomas](#)
Casilda M. Balmaceda

[Chapter 57. Pineal Region Tumors](#)
Jeffrey N. Bruce, Casilda M. Balmaceda, Bennett M. Stein, and Michael R. Fetell

[Chapter 58. Tumors of the Pituitary Gland](#)
Jeffrey N. Bruce, Michael R. Fetell, and Pamela U. Freda

[Chapter 59. Congenital and Childhood Central Nervous System Tumors](#)
James H. Garvin Jr. and Neil A. Feldstein

[Chapter 60. Vascular Tumors and Malformations](#)
Robert A. Solomon, John Pile-Spellman, and J. P. Mohr

[Chapter 61. Metastatic Tumors](#)
Casilda M. Balmaceda

[Chapter 62. Spinal Tumors](#)
Paul C. McCormick, Michael R. Fetell, and Lewis P. Rowland

SECTION VII. TRAUMA

[Chapter 63. Head Injury](#)
Stephan A. Mayer and Lewis P. Rowland

[Chapter 64. Spinal Injury](#)
Joseph T. Marotta

[Chapter 65. Intervertebral Disks and Radiculopathy](#)
Paul C. McCormick

[Chapter 66. Cervical Spondylotic Myelopathy](#)

Lewis P. Rowland and Paul C. McCormick

[Chapter 67. Lumbar Spondylosis](#)

Lewis P. Rowland and Paul C. McCormick

[Chapter 68. Peripheral and Cranial Nerve Lesions](#)

Dale J. Lange, Werner Trojaborg, and Lewis P. Rowland

[Chapter 69. Thoracic Outlet Syndrome](#)

Lewis P. Rowland

[Chapter 70. Neuropathic Pain and Posttraumatic Pain Syndromes](#)

James H. Halsey

[Chapter 71. Radiation Injury](#)

Casilda M. Balmaceda and Steven R. Isaacson

[Chapter 72. Electrical and Lightning Injury](#)

Lewis P. Rowland

[Chapter 73. Decompression Sickness](#)

Leon D. Prockop

SECTION VIII. BIRTH INJURIES AND DEVELOPMENTAL ABNORMALITIES

[Chapter 74. Neonatal Neurology](#)

M. Richard Koenigsberger and Ram Kairam

[Chapter 75. Floppy Infant Syndrome](#)

Thornton B.A. Mason, II and Darryl C. De Vivo

[Chapter 76. Static Disorders of Brain Development](#)

Isabelle Rapin

[Chapter 77. Laurence-Moon-Biedl Syndrome](#)

Melvin Greer

[Chapter 78. Structural Malformations](#)

Melvin Greer

[Chapter 79. Marcus Gunn and Möbius Syndromes](#)

Lewis P. Rowland

SECTION IX. GENETIC DISEASES OF THE CENTRAL NERVOUS SYSTEM

[Chapter 80. Chromosomal Diseases](#)

Ching H. Wang

[Chapter 81. Disorders of Amino Acid Metabolism](#)

John H. Menkes

[Chapter 82. Disorders of Purine Metabolism](#)

Lewis P. Rowland

[Chapter 83. Lysosomal and Other Storage Diseases](#)

William G. Johnson

[Chapter 84. Disorders of Carbohydrate Metabolism](#)

Salvatore DiMauro

[Chapter 85. Glucose Transporter Protein Syndrome](#)

Darryl C. De Vivo

[Chapter 86. Hyperammonemia](#)

Rosario R. Trifiletti and Douglas R. Nordli, Jr.

[Chapter 87. Peroxisomal Diseases: Adrenoleukodystrophy, Zellweger Syndrome, and Refsum Disease](#)

Mia MacCollin and Darryl C. De Vivo

[Chapter 88. Organic Acidurias](#)

Stefano Di Donato and Graziella Uziel

[Chapter 89. Disorders of Metal Metabolism](#)

John H. Menkes

[Chapter 90. Acute Intermittent Porphyria](#)

Lewis P. Rowland

[Chapter 91. Neurological Syndromes with Acanthocytes](#)

Timothy A. Pedley and Lewis P. Rowland

[Chapter 92. Xeroderma Pigmentosum](#)

Lewis P. Rowland

[Chapter 93. Cerebral Degenerations of Childhood](#)

Eveline C. Traeger and Isabelle Rapin

[Chapter 94. Diffuse Sclerosis](#)

Lewis P. Rowland

[Chapter 95. Differential Diagnosis](#)

Eveline C. Traeger and Isabelle Rapin

SECTION X. DISORDERS OF MITOCHONDRIAL DNA

[Chapter 96. Mitochondrial Encephalomyopathies: Diseases of Mitochondrial DNA](#)

Salvatore DiMauro, Eric A Schon, Michio Hirano, and Lewis P. Rowland

[Chapter 97. Leber Hereditary Optic Neuropathy](#)

Myles M. Behrens and Michio Hirano

[Chapter 98. Mitochondrial Diseases with Mutations of Nuclear DNA](#)

Darryl C. De Vivo and Michio Hirano

SECTION XI. NEURO CUTANEOUS DISORDERS

[Chapter 99. Neurofibromatosis](#)

Arnold P. Gold

[Chapter 100. Encephalotrigeminal Angiomatosis](#)

Arnold P. Gold

[Chapter 101. Incontinencia Pigmenti](#)

Arnold P. Gold

[Chapter 102. Tuberous Sclerosis](#)

Arnold P. Gold

SECTION XII. PERIPHERAL NEUROPATHIES

[Chapter 103. General Considerations](#)

Norman Latov

[Chapter 104. Hereditary Neuropathies](#)

Robert E. Lovelace and Lewis P. Rowland

[Chapter 105. Acquired Neuropathies](#)

Dale J. Lange, Norman Latov and Werner Trojaborg

SECTION XIII. DEMENTIAS

[Chapter 106. Alzheimer Disease and Related Dementias](#)

Scott A. Small and Richard Mayeux

SECTION XIV. ATAXIAS

[Chapter 107. Hereditary Ataxias](#)

Susan B. Bressman, Timothy Lynch, and Roger N. Rosenberg

SECTION XV. MOVEMENT DISORDERS

[Chapter 108. Huntington Disease](#)

Stanley Fahn

[Chapter 109. Sydenham and Other Forms of Chorea](#)

Stanley Fahn

[Chapter 110. Myoclonus](#)

Stanley Fahn

[Chapter 111. Gilles de la Tourette Syndrome](#)

Stanley Fahn

[Chapter 112. Dystonia](#)

Stanley Fahn and Susan B Bressman

[Chapter 113. Essential Tremor](#)

Elan D. Louis and Paul E. Greene

[Chapter 114. Parkinsonism](#)

Stanley Fahn and Serge Przedborski

[Chapter 115. Progressive Supranuclear Palsy](#)

Paul E. Greene

[Chapter 116. Tardive Dyskinesia and Other Neuroleptic-Induced Syndromes](#)

Stanley Fahn and Robert E. Burke

SECTION XVI. SPINAL CORD DISEASES

[Chapter 117. Hereditary and Acquired Spastic Paraplegia](#)

Lewis P. Rowland

[Chapter 118. Hereditary and Acquired Motor Neuron Diseases](#)

Lewis P. Rowland

[Chapter 119. Syringomyelia](#)

Elliott L. Mancall and Paul C. McCormick

SECTION XVII. DISORDERS OF THE NEUROMUSCULAR JUNCTION

[Chapter 120. Myasthenia Gravis](#)

Audrey S. Penn and Lewis P. Rowland

[Chapter 121. Lambert-Eaton Syndrome](#)

Audrey S. Penn

[Chapter 122. Botulism and Antibiotic-Induced Neuromuscular Disorders](#)

Audrey S. Penn

[Chapter 123. Acute Quadriplegic Myopathy](#)

Michio Hirano

SECTION XVIII. MYOPATHIES

[Chapter 124. Identifying Disorders of the Motor Unit](#)

Lewis P. Rowland

[Chapter 125. Progressive Muscular Dystrophies](#)

Lewis P. Rowland

[Chapter 126. Familial Periodic Paralysis](#)

Lewis P. Rowland

[Chapter 127. Congenital Disorders of Muscle](#)

Lewis P. Rowland

[Chapter 128. Myoglobinuria](#)

Lewis P. Rowland

[Chapter 129. Muscle Cramps and Stiffness](#)

Robert B. Layzer and Lewis P. Rowland

[Chapter 130. Dermatomyositis](#)

Lewis P. Rowland

[Chapter 131. Polymyositis, Inclusion Body Myositis, and Related Myopathies](#)
Lewis P. Rowland

[Chapter 132. Myositis Ossificans](#)
Lewis P. Rowland

SECTION XIX. DEMYELINATING DISEASES

[Chapter 133. Multiple Sclerosis](#)
James R. Miller

[Chapter 134. Marchiafava-Bignami Disease](#)
James R. Miller

[Chapter 135. Central Pontine Myelinolysis](#)
Gary L. Bernardini and Elliott L. Mancall

SECTION XX. AUTONOMIC DISORDERS

[Chapter 136. Neurogenic Orthostatic Hypotension and Autonomic Failure](#)
Louis H. Weimer

[Chapter 137. Acute Autonomic Neuropathy](#)
Louis H. Weimer

[Chapter 138. Familial Dysautonomia](#)
Alan M. Aron

SECTION XXI. PAROXYSMAL DISORDERS

[Chapter 139. Migraine and Other Headaches](#)
Neil H. Raskin

[Chapter 140. Epilepsy](#)
Timothy A. Pedley, Carl W. Bazil, and Martha J. Morrell

[Chapter 141. Febrile Seizures](#)
Douglas R. Nordli, Jr. and Timothy A. Pedley

[Chapter 142. Neonatal Seizures](#)
Douglas R. Nordli, Jr. and Timothy A. Pedley

[Chapter 143. Transient Global Amnesia](#)
John C.M. Brust

[Chapter 144. Meniere Syndrome](#)
Jack J. Wazen

[Chapter 145. Sleep Disorders](#)
June M. Fry

SECTION XXII. SYSTEMIC DISEASES AND GENERAL MEDICINE

[Chapter 146. Endocrine Diseases](#)
Gary M. Abrams and Earl A. Zimmerman

[Chapter 147. Hematologic and Related Diseases](#)
Kyriakos P. Papadopoulos and Casilda M. Balmaceda

[Chapter 148. Hepatic Disease](#)
Neil H. Raskin and Lewis P. Rowland

[Chapter 149. Cerebral Complications of Cardiac Surgery](#)
Eric J. Heyer and Lewis P. Rowland

[Chapter 150. Bone Disease](#)
Roger N. Rosenberg

[Chapter 151. Renal Disease](#)
Neil H. Raskin

[Chapter 152. Respiratory Care: Diagnosis and Management](#)
Stephan A. Mayer and Matthew E. Fink

[Chapter 153. Paraneoplastic Syndromes](#)
Lewis P. Rowland

[Chapter 154. Nutritional Disorders: Vitamin B₁₂ Deficiency, Malabsorption, and Malnutrition](#)
Lewis P. Rowland and Bradford P. Worrall

[Chapter 155. Vasculitis Syndromes](#)
Lewis P. Rowland

[Chapter 156. Neurologic Disease During Pregnancy](#)
Alison M. Pack and Martha J. Morrell

SECTION XXIII. ENVIRONMENTAL NEUROLOGY

[Chapter 157. Alcoholism](#)
John C.M. Brust

[Chapter 158. Drug Dependence](#)
John C.M. Brust

[Chapter 159. Iatrogenic Disease](#)
Lewis P. Rowland

[Chapter 160. Complications of Cancer Chemotherapy](#)
Massimo Corbo and Casilda M. Balmaceda

[Chapter 161. Occupational and Environmental Neurotoxicology](#)
Lewis P. Rowland

[Chapter 162. Abuse of Children](#)
Claudia A. Chiriboga

[Chapter 163. Falls in the Elderly](#)

SECTION XXIV. REHABILITATION

[Chapter 164. Neurologic Rehabilitation](#)
Laura Lennihan and Glenn M. Seliger

SECTION XXV. ETHICAL AND LEGAL GUIDELINES

[Chapter 165. End-of-Life Issues in Neurology](#)
Lewis P. Rowland

CONTRIBUTING AUTHORS

Gary M. Abrams, M.D.

Associate Professor
Department of Neurology
University of California
505 Parnassus Avenue
San Francisco, California 94143, and
Chief, Department of Neurology/Rehabilitation
University of California, San Francisco/Mt. Zion Medical Center
1600 Divisadero Street
San Francisco, California 94115

Alan M. Aron, M.D.

Professor of Pediatrics and Clinical Neurology
Departments of Neurology and Pediatrics
Mount Sinai-New York University Medical Center, and
Director, Attending Neurologist, and Attending Pediatrician
Department of Pediatric Neurology
Mount Sinai Hospital
One Gustave Levy Place
New York, New York 10029

Casilda M. Balmaceda, M.D.

Assistant Professor of Neurology
Columbia University College of Physicians and Surgeons
Assistant Attending Neurologist
New York-Presbyterian Hospital
Neurological Institute
Columbia-Presbyterian Medical Center
710 West 168th Street
New York, New York 10032

Carl W. Bazil, M.D., Ph.D.

Assistant Professor of Neurology
Columbia University College of Physicians and Surgeons
Assistant Attending Neurologist
New York-Presbyterian Hospital
Neurological Institute
Columbia-Presbyterian Medical Center
710 West 168th Street
New York, New York 10032

Myles M. Behrens, M.D.

Professor of Clinical Ophthalmology
Columbia University College of Physicians and Surgeons
Attending Ophthalmologist
New York-Presbyterian Hospital
Eye Institute Room 114
635 165th Street, Box 71
New York, New York 10032

Gary L. Bernardini, M.D., Ph.D.

Associate Professor of Neurology
Albany Medical College
Director
Neurological Intensive Care Unit
Albany Medical Center
47 New Scotland Avenue
Albany, New York 12208

Susan B. Bressman, M.D.

Chair
Department of Neurology
Beth Israel Hospital
Phillips Ambulatory Care Center
10 Union Square East, Suite 2Q
New York, New York 10032

Carolyn Barley Britton, M.D.

Associate Professor of Clinical Neurology
Columbia University College of Physicians and Surgeons
Associate Attending Neurologist
New York-Presbyterian Hospital
Neurological Institute
Columbia-Presbyterian Medical Center
710 West 168th Street
New York, New York 10032

Jeffrey N. Bruce, M.D.

Associate Professor of Neurological Surgery
Associate Attending Neurological Surgeon
Neurological Institute
Columbia-Presbyterian Medical Center
710 West 168th Street
New York, New York 10032

John C. M. Brust, M.D.

Professor of Clinical Neurology
Department of Neurology
Columbia University College of Physicians and Surgeons

Attending Neurologist
New York-Presbyterian Hospital
710 West 168th Street
New York, New York 10032, and
Director, Department of Neurology
Harlem Hospital Center
506 Lenox Avenue
New York, New York 10037

Robert E. Burke, M.D.
Professor of Neurology
Attending Neurologist
Columbia University College of Physicians and Surgeons
Black Building
650 West 168th Street, 3rd Floor
New York, New York 10032

Abba L. Cargan, M.D.
Assistant Professor of Neurology
Columbia University College of Physicians and Surgeons
Assistant Attending Neurologist
New York-Presbyterian Hospital
Neurological Institute
Columbia-Presbyterian Medical Center
710 West 168th Street
New York, New York 10032

Stephen Chan, M.D.
Assistant Professor of Radiology
Assistant Attending Neurologist (Neuroradiology)
Columbia University College of Physicians and Surgeons
Milstein Hospital Building
177 Fort Washington Avenue
New York, New York 10032

Claudia A. Chiriboga, M.D.
Assistant Professor of Neurology
Columbia University College of Physicians and Surgeons
Assistant Attending Neurologist
New York-Presbyterian Hospital
Neurological Institute
Columbia-Presbyterian Medical Center
710 West 168th Street
New York, New York 10032

Massimo Corbo
Assistant Professor of Neurology
Department of Neurology
San Raffaele Hospital
Scientific Institute of Milan
20132 Milan, Italy

Darryl C. De Vivo, M.D.
Sidney Carter Professor of Neurology
Professor of Pediatrics
Columbia University College of Physicians and Surgeons
Attending Neurologist and Pediatrician
Chief, Division of Pediatric Neurology
Neurological Institute
Columbia-Presbyterian Medical Center
710 West 168th Street
New York, New York 10032

Robert DeLaPaz, M.D.
Professor of Radiology
Columbia University College of Physicians and Surgeons
Attending Radiologist
Director, Division of Neuroradiology
New York-Presbyterian Hospital
Milstein Hospital Building
Columbia-Presbyterian Medical Center
177 Fort Washington Avenue
New York, New York 10032

Stefano Di Donato, M.D.
Department of Pediatric Neurology
Istituto Nazionale Neurologico C. Besta
Via Celoria, 11
Milano, 20133
Italy

Salvatore DiMauro, M.D.
Lucy G. Moses Professor
Department of Neurology
Columbia University College of Physicians and Surgeons
630 West 168th Street
New York, New York 10032

Mitchell S.V. Elkind, M.D.
Assistant Professor of Neurology
Columbia University College of Physicians and Surgeons
Assistant Attending Neurologist

New York-Presbyterian Hospital
Neurological Institute
Columbia-Presbyterian Medical Center
710 West 168th Street
New York, New York 10032

Ronald G. Emerson, M.D.

Professor of Clinical Neurology and Clinical Pediatrics
Columbia University College of Physicians and Surgeons
Attending Neurologist
New York-Presbyterian Hospital
Columbia-Presbyterian Medical Center
Neurological Institute
710 West 168th Street
New York, New York 10032

Stanley Fahn, M.D.

H. Houston Merritt Professor of Neurology
Columbia University College of Physicians and Surgeons
Attending Neurologist
Chief, Division of Movement Disorder
New York-Presbyterian Hospital
Neurological Institute
710 West 168th Street
New York, New York 10032

Neil A. Feldstein, M.D.

Assistant Professor of Neurological Surgery
Assistant Attending Neurosurgeon
Neurological Institute
Columbia-Presbyterian Medical Center
710 West 168th Street
New York, New York 10032

Michael R. Fetell, M.D.

Professor of Clinical Neurology and Neurosurgery
Attending Neurologist
Neurological Institute
Columbia-Presbyterian Medical Center
710 West 168th Street
New York, New York 10032

Robert L. Fine, M.D.

Herbert Irving Associate Professor of Medicine
Director, Medical Oncology Division
Columbia University College of Physicians and Surgeons
Associate Attending Physician in Medicine
New York-Presbyterian Hospital
650 West 168th Street
New York, New York 10032

Matthew E. Fink, M.D.

Department of Neurology
Albert Einstein College of Medicine
President, Chief Executive Officer, and Attending Neurologist
Beth Israel Medical Center
First Avenue at 16th Street
New York, New York 10003

Robert A. Fishman, M.D.

Professor Emeritus
Department of Neurology
University of California, San Francisco, and
Attending Neurologist
Department of Neurology
University of California, San Francisco Hospitals
505 Parnassus Avenue
San Francisco, California 94143

Pamela U. Freda

Associate Professor of Clinical Medicine
Department of Medicine
Columbia University College of Physicians and Surgeons
630 West 168th Street
New York, New York 10032, and
Assistant Attending Physician
Department of Medicine
New York-Presbyterian Hospital
622 West 168th Street
New York, New York 10032

June M. Fry M.D., Ph.D.

Professor
Department of Neurology
MCP Hahnemann University
3200 Henry Avenue
Philadelphia, Pennsylvania 19129, and
Director of Sleep Medicine
Department of Neurology
Medical College of Pennsylvania Hospital
3300 Henry Avenue

Philadelphia, Pennsylvania 19129

James H. Garvin Jr., M.D., Ph.D.

*Professor of Clinical Pediatrics
Columbia University College of Physicians and Surgeons
Attending Pediatrician
New York-Presbyterian Hospital
630 West 168th Street
New York, New York 10032*

Sid Gilman, M.D.

*William J. Herdman Professor and Chair
Department of Neurology
University of Michigan, and
Chief, Neurology Service
University of Michigan Hospitals
1500 East Medical Center Drive
Ann Arbor, Michigan 48109-0316*

Arnold P. Gold, M.D.

*Professor of Clinical Neurology and Professor of Clinical Pediatrics
Columbia University College of Physicians and Surgeons
Attending Neurologist and Pediatrician
New York-Presbyterian Hospital
Neurological Institute
Columbia-Presbyterian Medical Center
710 West 168th Street
New York, New York 10032*

Paul E. Greene, M.D.

*Assistant Professor of Neurology
Columbia University College of Physicians and Surgeons
Assistant Attending Neurologist
New York-Presbyterian Hospital
Neurological Institute
Columbia-Presbyterian Medical Center
710 West 168th Street
New York, New York 10032*

Melvin Greer, M.D.

*Professor and Chairman
Department of Neurology
University of Florida College of Medicine
Box 100236
Gainesville, Florida 32610*

Alexander Halim, Ph.D.

*Department of Neurology
Columbia University College of Physicians and Surgeons
Neurological Institute
Columbia-Presbyterian Medical Center
710 West 168th Street
New York, New York 10032*

James H. Halsey, M.D.

*Professor of Clinical Neurology
Department of Neurology
Columbia University College of Physicians and Surgeons
710 West 168th Street
New York, New York 10032*

Arthur P. Hays, M.D.

*Associate Professor of Clinical Neuropathology
Department of Pathology
Columbia University College of Physicians and Surgeons
630 West 168th Street
New York, New York 10032, and
Associate Attending in Pathology
Department of Pathology
New York Presbyterian Hospital
622 West 168th Street
New York, New York 10032*

Eric J. Heyer, M.D.

*Associate Professor of Clinical Anesthesiology and Clinical Neurology
Associate Attending Anesthesiologist
Columbia University College of Physicians and Surgeons
630 West 168th Street
New York, New York 10032*

Michio Hirano, M.D.

*Herbert Irving Assistant Professor of Neurology
Assistant Attending Neurologist
Department of Neurology
Columbia University College of Physicians and Surgeons
630 West 168th Street
New York, New York 10032*

Stephen R. Isaacson

*Associate Professor
Department of Radiation Oncology
Columbia University College of Physicians and Surgeons*

622 West 168th Street
New York, New York 10032

William G. Johnson, M.D.

Professor of Neurology
University of Medicine and Dentistry of New Jersey
Robert Wood Johnson Medical School
675 Hoes Lane
Piscataway, New Jersey 08854-5635

Burk Jubelt, M.D.

Professor and Chairman
Department of Neurology
Professor
Department of Microbiology/Immunology
SUNY Upstate Medical University
Chief
Department of Neurology
University Hospital
750 East Adams Street
Syracuse, New York 13210

Ram Kairam, M.D.

Assistant Professor of Clinical Pediatrics and Clinical Neurology
Columbia University College of Physicians and Surgeons
Lincoln Hospital
234 E. 149th Street
Bronx, New York 10451

M. Richard Koenigsberger, M.D.

Professor of Clinical Neurosciences
University of Medicine and Dentistry of New Jersey
185 S. Orange Avenue
Newark, New Jersey 07103

Dale J. Lange, M.D.

Associate Professor of Clinical Neurology
Associate Attending Neurologist
Neurological Institute
Columbia-Presbyterian Medical Center
710 West 168th Street
New York, New York 10032

Norman Latov, M.D., Ph.D.

Professor of Neurology
Attending Neurologist
Director, Peripheral Neuropathy Division
Neurological Institute
Columbia-Presbyterian Medical Center
710 West 168th St.
New York, New York 10032

Robert B. Layzer, M.D.

Professor of Neurology Emeritus
University of California, San Francisco
Box 0114
San Francisco, California 94143

Laura Lennihan, M.D.

Associate Professor of Clinical Neurology
Associate Attending Neurologist
New York-Presbyterian Hospital
710 West 168th Street
New York, New York 10032, and
Chief, Department of Neurology
Helen Hayes Hospital
Route 9W
West Haverstraw, New York 10993

Elan D. Louis, M.D.

Assistant Professor of Neurology
Columbia University College of Physicians and Surgeons
Assistant Attending Neurologist
New York-Presbyterian Hospital
Neurological Institute
Columbia-Presbyterian Medical Center
710 West 168th Street
New York, New York 10032

Robert E. Lovelace, M.D.

Professor of Neurology
Attending Neurologist
Neurological Institute
Columbia-Presbyterian Medical Center
710 West 168th Street
New York, New York 10032

Timothy Lynch, M.R.C.P.I., M.R.C.P. (London)

Consultant Neurologist
The Mater Misericordiae Hospital
Eccles Street

Dublin 7, Ireland

Mia MacCollin, M.D.

Assistant Professor
Department of Neurology
Harvard Medical School
Boston, Massachusetts 02115, and Assistant Professor
Department of Neurology
Massachusetts General Hospital
Neuroscience Center, MGH East

PREFACE

H. Houston Merritt first published this *Textbook of Neurology* in 1955. He was the sole author. The book became popular, and he revised it himself through the fourth edition. As the mass of information increased, he finally accepted contributions from colleagues for the fifth edition. Even then, he wrote most of the book himself, and he continued to do so for the sixth edition despite serious physical disability. He died in 1979, just as the sixth edition was released for distribution.

The seventh edition, published in 1984, was prepared by seventy of Merritt's students. Thirty of them headed neurology departments and others had become distinguished clinicians, teachers, and investigators. That edition was a landmark in the history of neurology. It documented the human legacy of a singular and great leader whose career set models for clinical investigation (when it was just beginning), clinical practice, teaching, editing books and journals, administering schools and departments, and commitment to national professional and voluntary organizations.

We now provide the tenth edition. The list of authors has changed progressively, as a dynamic book must do. Yet the ties to Merritt persist. Many of his personal students are still here and their students, Merritt's intellectual grandchildren, are appearing in increasing numbers.

Merritt's Neurology is intended for medical students, house officers, practicing neurologists, non-neurologist clinicians, nurses, and other healthcare workers. We hope it will be generally useful in providing the essential facts about common and rare diseases or conditions that are likely to be encountered.

We have tried to maintain Merritt's literary attributes: direct, clear, and succinct writing; emphasis on facts rather than unsupported opinion (now called "evidence-based medicine"); and ample use of illustrations and tables.

The book now faces competition from other books, including electronic textbooks, but its success is based on several attributes. A book, unlike a computer, can be taken and used almost anywhere. A one-volume textbook is handier, more mobile, and less expensive than the multivolume sets that now dot the scene. Briefer paperbacks provide less information and fewer references.

This edition includes comprehensive revisions demanded by the progress of research in epilepsy, Parkinson disease and other movement disorders, stroke, dementia, critical care, multiple sclerosis, ataxias, neurology of pregnancy, prion diseases, mitochondrial diseases, autonomic diseases, neuro-oncology, neurotoxicology, peripheral neuropathies, muscular dystrophies, cerebral complications of cardiac surgery, transplantation and imaging. New chapters have been added on prion diseases, CSF hypotension, superficial siderosis, glucose transporter deficiency, and end-of-life issues.

In almost every chapter, the impact of molecular genetics has left its mark in much updating. The progress of medical science has produced monographs on each of these subjects; a challenge to our authors has been the need to transmit the essential information without unduly enlarging the textbook.

We have retained the general organization of previous editions, including arbitrary decisions about the placement of some subjects. Does the discussion of seizures or multiple sclerosis in pregnancy belong in chapters on pregnancy, epilepsy or multiple sclerosis? Is the Lambert-Eaton syndrome best described in a chapter on neuromuscular disorders or one on paraneoplastic syndromes? We have opted for redundancy on these issues. It makes the book a bit longer than it might be otherwise, but the reader does not have to keep flipping pages to find the information.

The impact of molecular genetics has left other marks. Do we continue to organize the book by clinical syndromes and diseases or do we group by the nature of the mutation? "Channelopathies" or "neuromuscular disease" for Lambert-Eaton disease? "Channelopathy for familial hemiplegic migraine" or a form of headache? "Nondystrophic myotonia" or periodic paralysis for the hyperkalemic type? Triplet repeat or ataxia or spinobulbar muscular atrophy? We have opted for the clinical classification while recognizing that we are on the verge of understanding the pathogenesis of these increasingly scrutable diseases.

Another uncertainty involves eponyms: use apostrophe or not? There is no consensus in medical publishing because not everyone recognizes there is a problem. Neurology journals and the influential *New England Journal of Medicine* have not changed, but journals devoted to genetics or radiology have dropped the apostrophe and even the AMA journals are coming around. The Council of Biology Editors has taken a strong stand against the use of the possessive form.

It is not only the possessive inference that is objectionable. The legendary humorist A. J. Liebling once wrote: "I had Bright's disease and he had mine." In other usage, the nominal adjective is not the possessive; no one objects to Madison Avenue, Harvard University, Nobel Prize, or Kennedy Center. And there are other challenges, including the grating sibilance of "Duchenne's dystrophy" and the inconsistency of people who use that term, sometimes with the apostrophe and sometimes without. In the neuromuscular community, "Duchenne dystrophy" is surely preferred. And consider our hapless heroes whose names end in an "s": Graves, Kufs, Gowers, Menkes and others become incorrectly singular when the apostrophe is inserted (creating the nonexistent "Kuf's disease"). If the possessive is added at the end, something sounds wrong in "Graves's disease."

We have therefore followed the general rules of Victor McKusick in dealing with eponyms, giving general preference to the nonpossessive form without being totally rigid about it. Often, an inserted "the" can smoothly precede the eponym, especially in hyphenated compounds such as "the Guillain-Barré syndrome." Nevertheless, as McKusick states: "some nonpossessive terms, because of long usage in the possessive, roll off the tongue awkwardly—e.g., the Huntington disease, the Wilson disease, the Hodgkin disease, etc." I myself have a hard time saying "Bell palsy." But Huntington disease, Alzheimer disease, Parkinson disease, and Hodgkin disease are heard with increasing frequency, even without a preceding "the". Once the nonpossessive form is used in conversation, it is more likely to sound natural.

In another tribute to the tremendous impact of Victor McKusick, we have retained the practice of giving his catalog numbers for genetic diseases. Readers can then find the history of the syndrome and current research data in the catalog, which is now online. In this day of gender-neutral writing, it is awkward to use the acronym MIM for *Mendelian Inheritance in Man*. It seems too late to change that historic title, but "Human Mendelian Inheritance" would be euphonic.

On the other hand, the stiff-man syndrome remains a problem. Papers entitled "stiff-man syndrome in a woman" or "in a boy" ought to be fixed and "stiff-person syndrome" is just plain awkward. My personal attempts to use the eponym, "Moersch-Woltman syndrome" have had zero success, partly because the names do not trip lightly off the lip, and reversing the order is no better.

We thank all the authors for their devoted and skillful work. In the editor's office, Sheila Crescenzo has once again kept her head when I was losing mine, and she remained patient when I misplaced pages. She has been remarkably skillful in tracking correspondence and keeping multiple revisions of the same chapter in order. Terrance Gabriel was again a valuable resource in updating references throughout the book. At Lippincott Williams & Wilkins, Joyce Murphy supervised editing and production. Robin Cook was an excellent production editor. Charles Mitchell has had overall responsibility for the publisher. Their combined efforts have resulted in the handsome volume.

We formally dedicate the book to H. Houston Merritt. I personally dedicate it also to all the spouses and children of all the contributors, especially to Esther E. Rowland; our children, Andrew, Steven, and Joy; and our grandchildren, Mikaela, David Liam, Cameron Henry, and Mariel Rowland. All of them, Rowlands and others, have suffered neglect because of the contributors' clinical research and writing that provide the substance and content of this book.

ABBREVIATIONS

AchR	Acetyl choline receptor
AIDS	Acquired immunodeficiency syndrome
ALS	Amyotrophic lateral sclerosis
BAER	Brainstem auditory evoked response
BMD	Becker muscular dystrophy
C3	A specific component of complement
CIDP	Chronic inflammatory demyelinating Polyneuropathy
CJD	Creutzfeldt-Jakob disease
CK	Creatine kinase
CMT	Charcol-Marie-Tooth disease
CMV	Cytomegalovirus
CNS	Central nervous system
CPS	Complex partial seizures
CSF	Cerebrospinal fluid
CT	Computed tomography
DMD	Duchenne muscular dystrophy
DNA	Deoxyribonucleic acid
ECG	Electrocardiogram
EEK	Electroencephalography
EMG	Electromyography
ESR	Erythrocyte sedimentation rate
FSH	Facioscapulohumeral muscular Dystrophy
GBS	Guillain-Barré syndrome
GM1	A specific neural ganglioside
GSS	Gerstmann-Sträussler-Scheinker Disease
HD	Huntington disease
HIV	Human immunodeficiency virus
IVIG	Intravenous immunoglobulin therapy
KSS	Kearns-Sayre-syndrome
LHON	Leber hereditary optic neuropathy
MAG	Myelin-associated glycoprotein
MELAS	Mitochondrial encephalopathy with lactic acidosis and stroke
MERRF	Myoclonus epilepsy with ragged red fibers
MRA	Magnetic resonance angiography
MRI	Magnetic resonance imaging
MS	Multiple sclerosis
mtDNA	Mitochondrial DNA
MyD	Myotomic muscular dystrophy
NARP	Neuropathy, ataxia, retinitis pigmentosa
NPH	Normal pressure hydrocephalus
PET	Positron emission tomography
PML	Progressive multifocal leukoencephalopathy
POEMS	Syndrome of polyneuropathy, organomegaly, endocrinopathy, monoclonal paraproteinemia, and skin changes
RNA	Ribonucleic acid
SPECT	Single-photon emission computed tomography
SSER	Somatosensory evoked response
TIA	Transient ischemic attack
VER	Visual evoked response

SECTION I. SYMPTOMS OF NEUROLOGIC DISORDERS

CHAPTER 1. DELIRIUM AND DEMENTIA

SCOTT A. SMALL AND RICHARD MAYEUX

[Delirium](#)
[Dementia](#)
[Suggested Readings](#)

Delirium and dementia are two of the most common disorders of elderly patients, although both conditions may occur at any age. *Delirium* is the acute confusional state that may accompany infections, fever, metabolic disorders, and other medical or neurologic diseases. *Dementia*, in contrast, is usually chronic and progressive, and is usually caused by degenerative diseases of the brain, multiple strokes, or chronic infection. The most significant difference, however, is that delirium manifests itself by a fluctuating mental state, whereas patients suffering from dementia are usually alert and aware until late in the course of the disease.

DELIRIUM

The features of delirium were originally described by Hippocrates. Delirium refers to a global mental dysfunction marked by a disturbance of consciousness, especially reduced awareness of the environment and inability to maintain attention. Associated features include disruption of the sleep–wake cycle, drowsiness, restlessness, incoherence, irritability, emotional lability, perceptual misinterpretations (illusions), and hallucinations. Symptoms appear within hours or days and fluctuate, often worsening at night. Other characteristics that lead to the classification of a mental state as delirium include impairment of memory and intellectual function, the presence of a medical or neurologic condition to which the mental impairment is secondary, the disappearance of mental impairment if the primary medical or neurologic disorder is reversed, and the effect of the primary disorder on the brain, which is diffuse rather than focal.

Delirium is involved in a wide range of clinical states. Almost any severe acute medical or surgical condition, under the right circumstances, can cause delirium. Common causes can be divided into primary cerebral disease and systemic illness. Primary brain disorders include head injury, stroke, raised intracranial pressure, infection, and epilepsy. Systemic illnesses may be infectious, cardiovascular, endocrine, or toxic-metabolic.

Delirium tremens occurs only in people addicted to alcohol. It develops 24 to 48 hours after withdrawal from alcohol. Onset is marked by confusion, agitation, and hyperactivity. Memory is affected, and hallucinations are prominent. Autonomic hyperactivity results in tachycardia and high fever. If untreated, delirium tremens can be fatal.

The following drugs can cause delirium:

Atropine and related compounds
Barbiturates
Bromides
Chlordiazepoxide (Librium)
Chloral hydrate
Cimetidine and related compounds
Clonidine
Cocaine
Diazepam
Digitalis
Dopamine agonists
Ethanol
Flurazepam
Glutethimide
Haloperidol and other neuroleptics
Lithium
Mephenytoin (Mesantoin)
Meprobamate
Methyldopa
Opioids
Phencyclidine hydrochloride (PCP)
Phenytoin sodium (Dilantin)
Prednisone
Propranolol
Tricyclic antidepressants

In elderly patients, anticholinergic and hypnotic agents are particularly common causes of drug-induced delirium.

Delirium is a medical emergency because the disease or drug intoxication may be fatal if untreated, especially in the elderly. The appearance of delirium may double the risk of death within hours or weeks. Successful treatment of delirium eliminates much of this excess mortality. The two best predictors of fatal outcome are advanced age and the presence of multiple physical diseases.

The diagnostic evaluation is dictated by evidence in the patient's history and physical examination. First-line investigations include electrolytes, complete blood cell count, erythrocyte sedimentation rate (ESR), liver and thyroid function tests, toxicology screen, syphilis serology, blood cultures, urine culture, chest x-ray, and electrocardiogram (ECG). If the cause cannot be determined from these tests, additional investigations to consider include neuroimaging, cerebrospinal fluid (CSF) analysis, electroencephalogram (EEG), human immunodeficiency virus (HIV) antibody titer, cardiac enzymes, blood gases, and autoantibody screen.

The fluctuating state of awareness in delirium is accompanied by characteristic EEG changes. The varying level of attention parallels slowing of the background EEG rhythms. Triphasic waves may also be present. Appropriate treatment of the underlying disease improves both the patient's mental state and the EEG.

The management of delirium includes general supportive and symptomatic measures, as well as treatment of the specific underlying conditions.

DEMENTIA

Dementia is characterized by progressive intellectual deterioration that is sufficiently severe to interfere with social or occupational functions. Memory, orientation, abstraction, ability to learn, visuospatial perception, language function, constructional praxis, and higher executive functions, such as planning, organizing, and sequencing, are all impaired in dementia. In contrast to patients with delirium, those with dementia are alert and aware until late in the disease. Delirium is most often associated with intercurrent systemic diseases or drug intoxication, but dementia is usually due to a primary degenerative or structural disease of the brain. Alzheimer disease (AD) (see Section XIII: Dementias) accounts for more than 50% of cases of dementia in both clinical and autopsy series. In a community-based disease registry in New York City limited to people older than 65 years, the relative frequency of AD was similar to that in other clinical and autopsy series ([Table 1.1](#)). Parkinsonism (see [Chapter 114](#)) is sometimes associated with dementia, and diffuse Lewy body disease (see [Chapter 106](#)) is incorporated into this group. Huntington disease (see [Chapter 108](#)) is much less common but is still an important cause in the presenium. Less common degenerative diseases include Pick disease and frontotemporal dementia (see [Chapter 106](#)), progressive supranuclear palsy (see [Chapter 115](#)), and the hereditary ataxias (see [Chapter 107](#)).

Details of the differential diagnosis of diseases that cause dementia are provided in subsequent chapters. An exhaustive evaluation of patients with dementia is warranted. Although effective treatment for the primary degenerative diseases is limited, many other disorders that cause dementia are amenable to treatment that may arrest, if not reverse, the cognitive decline.

Mental Status Examination

The mental status evaluation is an essential part of every neurologic examination. It includes evaluation of awareness and consciousness, behavior, emotional state, content and stream of thought, and sensory and intellectual capabilities. Intellectual impairment is obvious in such florid conditions as delirium tremens or advanced dementia, but cognitive loss may not be evident in early delirium or dementia, unless the physician specifically tests mental status.

Traditionally, mental status examinations test *information* (e.g., where were you born? what is your mother's name? who is the president? when did World War II occur?), *orientation* (e.g., what place is this? what is the date? what time of day is it?), *concentration* (by use of serial reversals, e.g., spelling "world" backwards, naming the months of the year backwards beginning with December), *calculation* (e.g., doing simple arithmetic, making change, counting backwards by threes or sevens), and *reasoning, judgment, and memory* (e.g., identifying three objects and asking the patient to recall their names or telling a short story and asking the patient to try to recall it after a few minutes). The most important and sensitive items are probably orientation to time, serial reversals, and a memory phrase. The mini-mental status examination (MMSE) was introduced as a standard measure of cognitive function for both research and clinical purposes. This short examination can be administered at the bedside and completed in 10 minutes. Scores are assigned for each function ([Table 1.2](#)); the maximum score is 30 points. A score less than 24 is considered consistent with dementia. The MMSE, like all other brief mental status examinations, is not precise. Some investigators use a score of 26 as the cutoff to include milder forms of dementia and improve specificity. The MMSE tends to underdiagnose dementia in well-educated people and overdiagnose it in those with little schooling. Therefore, the MMSE should be used only as a first step. It does not replace the history or a more detailed examination of neuropsychologic function (see [Chapter 19](#)).

Diagnostic domain	Specific questions	Scoring
Orientation	1. What is the (day) (month) (year) (season)?	1 point for each correct response (maximum 5 points)
	2. What is the name of the patient (last, first) (age) (sex)?	2 points for each correct response (maximum 5 points)
Registration	Name three objects. State 1 second to six each. Then ask the patient to name all three after you have said them. Then repeat them and ask them to be named.	2 points if all three objects are repeated on the first attempt; 1 point for each repetition required
Attention/calculation	Serial sevens, or spelling "word" backwards	1 point for each correct response (maximum 5 points)
Recall	Ask for the three objects repeated for registration	1 point for each correct response (maximum 3 points)
Language	1. Ask patient to name a pencil and a watch	1 point for each correct response (maximum 2 points)
	2. Ask patient to repeat the following: "The ifs, ands, or buts"	2 points for correct response
	3. Ask patient to "take a paper in your right hand, hold it in your left, and put it on the floor"	3 points for correct response (maximum 3 points)
	4. Ask patient to read and obey the following: "Now, you are"	4 points for correct response
Visuospatial	5. Ask patient to write a sentence (copy a design)	5 points for correct response

Reprinted from Folstein et al., 1975.

TABLE 1.2. MINI-MENTAL STATUS EXAMINATION

In addition to testing mental status, it is necessary to test higher intellectual functions, including disorders of language (dysphasias); constructional apraxia; right–left disorientation; inability to carry out complex commands, especially those requiring crossing the midline (e.g., touching the left ear with the right thumb); inability to carry out imagined acts (ideomotor apraxia; e.g., "pretend that you have a book of matches and show me how you would light a match"); unilateral neglect; or inattention on double stimulation. These abnormalities are often associated with more focal brain lesions but may also be impaired in delirium or dementia. Examination of aphasia, apraxia, and agnosia is described in detail in [Chapter 2](#).

CHAPTER 2. APHASIA, APRAXIA, AND AGNOSIA

J. P. MOHR

[Aphasia](#)
[Apraxia](#)
[Agnosia](#)
[Suggested Readings](#)

APHASIA

Left-hemisphere dominance for speech and language applies to more than 95% of all populations studied. Right-hemisphere dominance in a right-handed person is rare enough to prompt case reports in the literature. Most left-handed persons show some disturbance in speech and language from either left- or right-hemisphere lesions, making predictions for hemisphere dominance for left-handed persons difficult to predict on an individual basis. The most predictable site for disturbances in speech and language are the regions in and bordering on the sylvian fissure of the hemisphere controlling the hand preferred for skilled movements. The farther from this zone that the lesion occurs, the less the lesion disturbs speech and language. The disturbances in speech and language resulting from a lesion form a group of disorders known as the *aphasias*.

The popular classifications of aphasia are based on classic views that the front half of the brain performs motor or executive functions and the back half sensory or receptive functions, with the two regions connected by pathways in the white matter. Classically, frontal lesions have been inferred to cause *motor aphasia*, those affecting the posterior regions cause *sensory aphasia*, and those interrupting the pathways between the frontal and posterior regions cause *conduction aphasia*. This formulation posits an anatomic functional loop with an afferent portion from the eyes and ears connecting to the visual and auditory system, an intrahemispheric portion through the white matter connecting the temporal with the frontal lobes (the arcuate fasciculus), and an efferent portion from the frontal lobes to the mouth and hand permitting, in its simplest function, words heard to be repeated aloud and words seen to be copied manually. Apart from the crude replication of sounds heard and shapes seen, of which any person even ignorant of the language conveyed by the sounds or forms is capable, meaning is thought to be conveyed to these shapes and sounds by access of the perisylvian region to the rest of the brain through intrahemispheric and transcallosal pathways. Interruption of these linkage pathways is postulated to produce *transcortical sensory aphasia*, in which words heard are repeated aloud or copied without comprehension, or *transcortical motor aphasia*, in which words can be repeated and copied but no spontaneous communication by conversation or writing occurs. Other “disconnections” have also been proposed for pathways to or from the periphery, which presumably would be in the subcortical white matter. Disconnections of incoming pathways bearing visual lexical information yield *pure alexia*; those of pathways conveying auditory material cause *pure word deafness*. The combination of these two disconnections causes *subcortical sensory aphasia*. Disconnections of efferent pathways from the motor speech zones produce *pure word mutism* or *subcortical motor aphasia*.

Although these generalizations are widely held to account for the major principles of cerebral organization, uncritical acceptance of the expected effects of certain lesion locations or prediction of lesion locations by the clinical features, as based on the classical formulas, often proves misleading for clinicians seeking the site and cause of a clinical disorder of speech and language. To avoid this problem, the material that follows emphasizes the clinical features that aid in local lesion diagnosis, with less emphasis on the classical concepts.

Motor Aphasias

An acute focal lesion (the most frequent and best known being an infarct) involving any portion of the insula or the individual gyrus forming the upper banks of the opercular cortex (from the anteroinferior frontal region to the anterior parietal) acutely disrupts the acquired skills involving the oropharyngeal, laryngeal, and respiratory systems that mediate speech, causing *mutism*. Writing may be preserved, although it is usually confined to a few simple words. Comprehension of words heard or seen is generally intact because these functions are largely subserved by posterior regions. The speech that emerges within minutes or days of the onset of motor aphasia consists mostly of crude vowels (*dysphonia*) and poorly articulated consonants (*dysarthria*). Disturbed coordination (*dyspraxia*) of speaking and breathing alters the rhythm of speech (*dysprosody*). This faulty intonation, stress, and phrasing of words and sentences is known collectively as *speech dyspraxia*. The language conveyed through this speech is usually only slightly disturbed, but the grammatical forms used in speaking or writing are sometimes simplified.

The more anterior that the lesion is along the operculum, the more speech dyspraxia predominates, especially with involvement of the inferior frontal region (Broca area) located adjacent to the sensorimotor cortex. When the sensorimotor cortex itself is affected, dysarthria and dysphonia are more prominent than dysprosody and dyspraxia. The errors in pronunciation may make it impossible to understand the language conveyed by the patient's speech, but they are not, strictly speaking, a language disorder.

When an acute lesion occurs more posteriorly along the sylvian operculum, the precise sensorimotor control over the positioning of the oropharynx may be impaired, causing unusual mispronunciations as well as mild dysphasia. The disturbed pronunciation is not simple dysarthria. Instead, the faulty oropharyngeal positionings yield sounds that differ from those intended (e.g., “dip” is said instead of “top”). The errors, analogous to the typing errors of a novice unfamiliar with the typewriter keyboard, are called *literal paraphasias*. The listener may mistake the utterances as language errors (*paraphasias*) or may be impressed with some of the genuine paraphasias and give the condition the name *conduction aphasia* (see the following). The patient's comprehension is intact despite the disordered pronunciation.

Stroke is the most common cause of acute lesions. The arrangement of the individual branches of the upper division of the sylvian artery favors the wide variety of focal embolic obstructions that produce this remarkable array of syndromes. The more specific that the speech abnormality is, the more limited is the focal infarction. Because the sensorimotor cortex is part of the same arterial supply of the upper division of the middle cerebral artery, the larger infarcts and other disorders such as *basal ganglia hemorrhages*, *abscesses*, *large tumors*, and *acute encephalitis* usually cause accompanying contralateral hemiparesis and hemisensory syndromes, making the diagnosis of perisylvian disease fairly easy. One disorder, known as *primary progressive aphasia*, appears to be an unusual form of atrophy, causing mainly a relentless decline in speech and language function without the accompanying motor, sensory, visual, or other clinical evidence of a large lesion affecting the main pathways serving these functions.

For speech and language, the smaller and more superficial that the injury is, the briefer and less severe is the disruption. Rapid improvement occurs even when the lesion involves sites classically considered to cause permanent speech and language disturbances, such as the foot of the third frontal gyrus (Broca area). The larger the acute lesion, the more evident is dysphasia and the longer is the delay before speech improves. In larger sylvian lesions, dysphasia is evident in disordered grammar, especially when tests involve single letters, spelling, and subtleties of syntax. Problems with syntax occur not only in speaking and writing but also in attempts to comprehend the meaning of words heard or seen. For example, the word “ear” is responded to more reliably than is “are,” “cat” more than “act,” and “eye” more than “I.” The language content of spontaneously uttered sentences is condensed, missing many of the filler words, causing *telegraphic speech*, or *agrammatism*. Agrammatism is an important sign of a major lesion of the operculum and insula. When the causative lesion involves many gyri, as with large infarcts, hemorrhages, and neoplasms or abscesses large enough to produce unilateral weakness, the reduction of both speech and comprehension is profound and is called *total aphasia*. Within weeks or months in cases of infarction and hemorrhage, comprehension improves, especially for nongrammatical forms, and speaking and writing seem to be affected more than listening and reading. This last syndrome, in which dysphasia is most evident in speaking and writing, is known as motor aphasia; the eponym *Broca aphasia* is often used. This syndrome emerges from an initial total aphasia as a late residual. It is not the usual acute syndrome of a circumscribed infarction, even when the lesion is confined to the pars opercularis of the inferior frontal gyrus (Broca area).

Sensory Aphasias

A different set of acute symptoms follows acute focal lesions of the posterior half of the temporal lobe and the posterior parietal and lateral occipital regions. Infarction is also the usual cause of the discrete syndromes, while hemorrhage, epilepsy, and acute encephalitis may account for sudden major syndromes. Even large lesions in these areas are usually far enough removed from the sensorimotor cortex so that hemiparesis and speech disturbances (e.g., dysprosody, dysarthria, or mutism) are only occasionally part of the clinical picture.

In patients with large posterior lesions, the effects are almost the reverse of the insular-opercular syndromes: Syntax is better preserved than semantics; speech is filled with small grammatical words, but the predicative words (i.e., words that contain the essence of the message) are omitted or distorted. Patients vocalize easily, engage in simple conversational exchanges, and even appear to be making an effort to communicate; however, little meaning is conveyed in the partial phrases,

disjointed clauses, and incomplete sentences. In the most severe form, speech is incomprehensible gibberish. Errors take the form of words that fail to occur (*omissions*), are mispronounced as similar-sounding words (*literal paraphasias*), or are replaced by others that have a similar meaning (*verbal paraphasias*). A similar disturbance affects understanding words heard or seen. These language disturbances may require prolonged conversation to be revealed in mild cases. Because this disturbance in language contrasts with motor aphasia, it is often labeled as sensory aphasia, or *Wernicke aphasia*, but neither syndrome is purely motor or sensory.

The posterior portions of the brain are more compact than the anterior portions. As a result, large infarctions or mass lesions from hemorrhage, abscess, encephalitis, or brain tumors in the posterior brain tend to cause similar clinical disorders with few variations in syndrome type. Contralateral hemianopia usually implies a deep lesion. When hemianopia persists for longer than about 1 week, the aphasia is likely to persist.

Highly focal lesions are uncommon and, when present, usually mean focal infarction. Those limited to the posterior temporal lobe usually produce only a part of the larger syndrome of sensory aphasia. Speech and language are only slightly disturbed, reading for comprehension may pass for normal, but auditory comprehension of language is grossly defective. This syndrome was classically known as *pure word deafness*. Patients with this disorder also usually reveal verbal paraphasias in spontaneous speech and disturbed silent reading comprehension. This syndrome might be better named the *auditory form of sensory aphasia*. It has a good prognosis, and useful clinical improvement occurs within weeks; some patients are almost normal.

A similarly restricted dysphasia may affect reading and writing, more so than auditory comprehension, because of a more posteriorly placed focal lesion that damages the posterior parietal and lateral occipital regions. Reading comprehension and writing morphology are strikingly abnormal. This syndrome has traditionally been known as *alexia with agraphia*, but spoken language and auditory comprehension are also disturbed (although less than reading and writing). A better label might be the *visual form of sensory aphasia*. It also has a good prognosis.

The more limited auditory and visual forms of Wernicke aphasia are rarely produced by mass lesions from any cause and tend to blend in larger lesions. Whether the major syndrome of sensory aphasia is a unified disturbance or a synergistic result of several separate disorders has not been determined.

Amnesic Aphasia

Anomia or its more limited form *dysnomia* is the term applied to errors in tests of naming. Analysis requires special consideration because the mere occurrence of naming errors is of less diagnostic importance than is the type of error made. In all major aphasic syndromes, errors in language production cause defective naming (*dysnomia*), taking the form of paraphasias of the literal (e.g., "flikt" for "flight") or verbal (e.g., "jump" for "flight") type. For this reason, it is not usually of diagnostic value to focus a clinical examination on dysnomias alone, as they have little value as signs of focal brain disease.

A pattern known as *amnesic dysnomia* has a greater localizing value. Patients act as though the name has been forgotten and may give functional descriptions instead. Invoking lame excuses, testimonials of prowess, claims of irrelevance, or impatience, patients seem unaware that the amnesic dysnomia is a sign of disease. The disturbance is common enough in normal individuals, but in those with disease it is prominent enough to interfere with conversation. Amnesic aphasia, when fully developed, is usually the result of disease of the deep temporal lobe gray and white matter. A frequent cause is Alzheimer disease, in which atrophy of the deep temporal lobe occurs early, and forgetfulness for names may be erroneously attributed to old age by the family. Identical symptoms may occur in the early stages of evolution of mass lesions from neoplasms or abscess but are rarely a sign of infarction in the deep temporal lobe. Other disturbances in language, such as those involving grammar, reading aloud, spelling, or writing, are usually absent, unless the responsible lesion encroaches on the adjacent temporal parietal or sylvian regions. When due to a mass lesion, the disturbance often evolves into the full syndrome of Wernicke aphasia.

Thalamic Lesions and Aphasia

An acute deep lesion on the side of the dominant hemisphere may cause dysphasia if it involves the posterior thalamic nuclei that have reciprocal connections with the language zones. Large mass lesions or slowly evolving thalamic tumors distort the whole hemisphere, making it difficult to recognize the components of the clinical picture. Small lesions are most often hematomas and are the usual cause of the sudden syndrome. As in delirium, consciousness fluctuates widely in this syndrome. As it fluctuates, language behavior varies from normal to spectacular usage. The syndrome may be mistaken for delirium due to metabolic causes (e.g., alcohol withdrawal). It is also important in the theory of language because the paraphasic errors are not due to a lesion that affects the cerebral surface, as was claimed traditionally. Prompt computed tomography usually demonstrates the thalamic lesion.

APRAXIA

The term *apraxia* (properly known as *dyspraxia* because the disorder is rarely complete) refers to disturbances in the execution of learned movements other than those disturbances caused by any coexisting weakness. These disorders are broadly considered to be the body-movement equivalents of the dysphasias and, like them, have classically been categorized into motor, sensory, and conduction forms.

Limb-kinetic or Innervatory Dyspraxia

This motor form of dyspraxia occurs as part of the syndrome of paresis caused by a cerebral lesion. Attempts to use the involved limbs reveal a disturbance in movement beyond that accounted for simply by weakness. Because attempted movements are disorganized, patients appear clumsy or unfamiliar with the movements called for in tasks such as writing or using utensils. Although difficult to demonstrate and easily overlooked in the presence of the more obvious weakness, innervatory dyspraxia is a useful sign to elicit because it indicates that the lesion causing the hemiparesis involves the cerebrum, presumably including the premotor region and other association systems. Dyspraxias of this type are thought to be caused by a lesion involving the cerebral surface or the immediately adjacent white matter; apraxia is not seen in lesions that involve the internal capsule or lower parts of the neuraxis.

Ideational Dyspraxia

Ideational dyspraxia is a different type of disorder altogether. Movements of affected body parts appear to suffer from the absence of a basic plan, although many spontaneous actions are easily carried out. This disorder is believed to be analogous to sensory aphasia (which features a breakdown of language organization despite continued utterance of individual words). The term is apparently derived from the simplistic notion that the lesion disrupts the brain region containing the motor plans for the chain of individual movements involved in complex behaviors such as feeding, dressing, or bathing. To the observer, patients appear uncertain about what to do next and may be misdiagnosed as confused. The lesion causing ideational dyspraxia is usually in the posterior half of the dominant hemisphere. The coexisting sensory aphasia often directs diagnostic attention away from the dyspraxia, which, like innervatory dyspraxia, is only rarely prominent enough to result in separate clinical recognition.

Ideomotor Dyspraxia

This form of dyspraxia is frequently encountered. The term derives from the notion that a lesion disrupts the connections between the region of the brain containing ideas and the region involved in the execution of movements. The disturbance is analogous to conduction aphasia: Motor behavior is intact when executed spontaneously, but faulty when attempted in response to verbal command. For movements to be executed by the nondominant hemisphere in response to dictated commands processed by the dominant hemisphere, the lesion could involve the presumed white-matter pathways through the dominant hemisphere to its motor cortex, the motor cortex itself, or the white matter connecting to the motor cortex of the nondominant hemisphere through the corpus callosum. Because so many presumed pathways are involved, ideomotor dyspraxia is common. The syndrome is most frequently encountered in the limbs served by the nondominant hemisphere when the lesion involves the convexity of the dominant hemisphere. Concomitant right hemiparesis and dysphasias, usually of the motor type, often occupy the physician's attention so that the ideomotor dyspraxia of the nondominant limbs passes without notice. Dysphasia may make it impossible to determine whether ideomotor dyspraxia is present, but, when mild, dyspraxia can be demonstrated by showing that patients cannot make movements on command, although they can mimic the behavior demonstrated by the examiner and execute it spontaneously at other times. The disturbances are most apparent for movements that involve the appendages (e.g., fingers, hands) or oropharynx. Axial and trunk movements are often spared.

AGNOSIA

When patients with a brain lesion respond to common environmental stimuli as if they had never encountered them previously, even though the primary neural

pathways of sensation function normally, this disorder is called an *agnosia*. Because the disturbance seen in response to a few stimuli is assumed to apply to others with similar properties, agnosias embrace specific classes of stimuli (e.g., agnosia for colors) or more global disturbances for a form of sensation (e.g., visual or auditory agnosia).

Such sweeping generalizations are usually unjustified in practice because careful examination often shows that the abnormality can be explained in some other way, including genuine unfamiliarity with the stimuli, faulty discrimination due to poor lighting, poor instructions from the examiner, or an overlooked end-organ failure (e.g., peripheral neuropathy, otosclerosis, cataracts). Faulty performance may also result from a dysphasia or dyspraxia. Errors arising from a dysphasia are easily understood; a dyspraxia may be more difficult to recognize. Sometimes, it is not clear whether dyspraxia produces agnosia, or vice versa. Posterior parietal lesions arising from cardiac arrest, neoplasm, or infections may impair cerebral control of the precise eye movements involved in the practiced exploration of a picture or other complex visual stimuli; the resulting chaotic but conjugate eye movements prevent the victim from naming or interacting properly with the stimuli. This abnormality seems to be a form of cerebral blindness (which patients may deny) and is an essential element of *Balint syndrome* (biparietal lesions causing disordered ocular tracking, bilateral hemineglect, and difficulties deciphering complex thematic pictures). Similar disturbances in skilled manual manipulation of objects may be documented in anterior parietal lesions that interfere with the ability to name or use an object properly.

When all these variables have been taken into account, a small group of patients may remain for whom the term *agnosia* may apply. Some neurologists deny that such a state exists, the errors presumably resulting from a combination of dementia and impaired primary sensory processing; others postulate anatomic disconnections due to lesions that lie between intact language areas and intact cerebral regions responsible for processing sensory input.

Two claimed clinical subtypes of visual agnosia embrace these differing theories of agnosia: *Apperceptive agnosia* refers to abnormality in the discrimination process, and *associative agnosia* implies an inability to link the fully discriminated stimulus to prior experience in naming or matching the stimulus to others. Clinically, patients with apperceptive visual agnosia are said to fail tests of copying a stimulus or cross-matching a stimulus with others having the same properties (i.e., different views of a car), whereas patients with the associative form can copy and cross-match; neither type can name the stimulus as such. Disturbances of the ability to respond to stimuli have been described for colors (*color agnosia*) and for faces (*prosopagnosia*). Although the definition of agnosia requires that a patient treat the stimuli as unfamiliar, the errors often pass almost unnoticed (i.e., dark colors are misnamed for other dark colors; names of famous people are mismatched with their pictures). In the auditory system, a similar disturbance may occur with a normal audiogram in discrimination of sounds (cortical deafness or *auditory agnosia*), including words (*pure word deafness* or *auditory agnosia for speech*). A patient's inability to recognize familiar objects by touch while still being able to recognize them by sight is referred to as *tactile agnosia*.

In practical clinical terms, the clinical diagnosis of agnosia warrants consideration when patients respond to familiar stimuli in an unusually unskillful manner, treat them as unfamiliar, or misname them for other stimuli having similar hue, shape, or weight, but do not show other signs of dysphasia or dyspraxia in other tests. The special testing is time-consuming but may yield a diagnosis of a disorder arising from lesions of the corpus callosum, the deep white matter, or the cerebrum adjacent to the main sensory areas. The usual cause is atrophy or metastatic or primary tumor. When the disorder develops further, the more obvious defects occur in formal confrontation visual field testing, and the "agnosia" is even more difficult to demonstrate.

CHAPTER 3. SYNCOPE AND SEIZURE

TIMOTHY A. PEDLEY AND DEWEY K. ZIEGLER

[Syncope](#)
[Seizures and Epilepsy](#)
[Suggested Readings](#)

Unexplained loss of consciousness is a common clinical problem. Seizure and syncope usually figure high on the list of diagnostic possibilities. The distinction is critical. This chapter considers clinical features that help discriminate among various causes of loss of consciousness and other episodic alterations in behavior and responsiveness.

SYNCOPE

Syncope refers to the transient alteration of consciousness accompanied by loss of muscular tone that results from an acute, reversible global reduction in cerebral blood flow. It is one of the most common causes of fading or complete loss of consciousness and accounts for about 3% of visits to emergency rooms. The prevalence of syncope has been as high as 47% in surveys of college students or young military flying personnel, and is equally high or higher in the elderly. In all forms of syncope, symptoms result from a sudden and critical decrease in cerebral perfusion. The causes of syncope are diverse ([Table 3.1](#)), and there is no uniformly satisfactory classification. Clinical features distinguish different types of syncope ([Table 3.2](#)).

- I. Neurocardiogenic syncope (direct cardiac inhibition)
 1. Vasovagal syncope
 2. Carotid sinus syndrome
 3. Micturition syncope
 4. Cough and other Valsalva-induced syncopes
 5. Emotional states
- II. Vasomotor syncope (inability to maintain peripheral vascular tone)
 1. Medications
 2. Postural changes
 3. Autonomic and peripheral neuropathies
 4. Peripheral vascular disease
 5. Neurodegenerative disease with orthostatic hypotension
 6. Blood loss
- III. Cardiac syncope
 1. Tachyarrhythmias
 2. Asystole and heart block
 3. Outflow obstruction
 4. Failing myocardium

TABLE 3.1. CAUSES OF SYNCOPE

Type	Admission mechanism after and during	Onset of episode	Relation to activity	Recovery to normal	ECG during episode	ECG after episode	Age of onset	Recovery of consciousness	ECG during episode	ECG after episode
Neurocardiogenic vasovagal micturition	Usually related to standing or coughing or other Valsalva maneuver	May be rapid or gradual	Usually occurs with standing or other Valsalva maneuver	Usually within minutes	Usually normal or sinus bradycardia	Usually normal or sinus bradycardia	All ages	Rapid	Normal	Normal
Vasomotor orthostatic hypotension	Usually related to standing or other Valsalva maneuver	May be rapid or gradual	Usually occurs with standing or other Valsalva maneuver	Usually within minutes	Usually normal or sinus bradycardia	Usually normal or sinus bradycardia	All ages	Rapid	Normal	Normal
Cardiac tachycardia	Usually related to standing or other Valsalva maneuver	May be rapid or gradual	Usually occurs with standing or other Valsalva maneuver	Usually within minutes	Usually normal or sinus bradycardia	Usually normal or sinus bradycardia	All ages	Rapid	Normal	Normal
Cardiac bradycardia	Usually related to standing or other Valsalva maneuver	May be rapid or gradual	Usually occurs with standing or other Valsalva maneuver	Usually within minutes	Usually normal or sinus bradycardia	Usually normal or sinus bradycardia	All ages	Rapid	Normal	Normal
Cardiac arrhythmias	Usually related to standing or other Valsalva maneuver	May be rapid or gradual	Usually occurs with standing or other Valsalva maneuver	Usually within minutes	Usually normal or sinus bradycardia	Usually normal or sinus bradycardia	All ages	Rapid	Normal	Normal
Cardiac structural	Usually related to standing or other Valsalva maneuver	May be rapid or gradual	Usually occurs with standing or other Valsalva maneuver	Usually within minutes	Usually normal or sinus bradycardia	Usually normal or sinus bradycardia	All ages	Rapid	Normal	Normal

TABLE 3.2. DIFFERENTIAL DIAGNOSIS OF TYPES OF SYNCOPE

Although syncope is generally a benign condition, nearly one-third of persons who experience syncope sustain injuries, including fractures of the hip or limbs. Additional morbidity may relate to the underlying cause of syncope.

Cardiovascular causes are most often encountered, although the exact mechanisms vary and include hypotension, arrhythmias, or direct cardiac inhibition ([Table 3.3](#)). Direct cardiac inhibition is responsible for the common *vasovagal* forms of syncope; bradycardia and hypotension are abnormal responses arising from activation of myocardial mechanoreceptors. Syncope can also occur when vasomotor tone is altered.

Cause	Patients (%)
Neurocardiogenic syncope	28
Vasovagal syncope	15
Carotid sinus syncope	5
Reflex syncope (cough, micturition)	15
Vagal reaction with trigeminal neuralgia	1

TABLE 3.3. CAUSES OF SYNCOPE

In reporting syncope, many patients say that they “passed out” or “had a spell.” Careful history taking, with attention to the meaning patients attach to words, is the cornerstone of differentiating syncope from other conditions. Important differential points for syncope include precipitating stimuli or situations, the nature of the fall, the character and evolution of prodromal symptoms, and the absence of any true postictal phase.

The following description is typical of most syncopal events. In the premonitory phase, the person feels light-headed and often apprehensive with a strong but ill-defined sensation of malaise. Peripheral vasoconstriction imparts a pale or ashen appearance, and the pulse is rapid. Profuse sweating is often accompanied by nausea and an urge to urinate or defecate. At this point, some individuals hyperventilate, which results in hypocapnia and further reduction in cerebral blood flow. Vision blurs and characteristically fades or “grays out” before consciousness is lost, but no alterations or distortions suggest an epileptic aura; there are no visual or olfactory hallucinations, or metamorphopsia. Response times slow, and the patient may feel detached or floating just before losing consciousness. Attacks usually occur when the person is standing or sitting and may be aborted if one can lie down or at least lower the head below the level of the heart.

If the attack proceeds, the patient loses tone in the muscles of the legs and trunk as consciousness is lost, but the fall is more of a swoon or limp collapse. While unconscious, the patient continues to be pale and sweaty; the limbs are flaccid. The period of unconsciousness is brief, lasting only seconds or a few minutes. If the hypoxia associated with syncope is severe, brief tonic posturing of the trunk or a few clonic jerks of the arms and legs (*convulsive syncope*) may be seen as the episode ends. Although these involuntary movements may superficially suggest a seizure, the absence of a typical tonic-clonic sequence, the prompt recovery, and other features of the attack lead to the correct diagnosis.

Pulse and blood pressure rapidly return to normal, and symptoms resolve promptly and completely if the patient is allowed to remain recumbent. Some patients feel weak and are briefly confused on recovery; incontinence is rare.

Neurocardiogenic (Vasovagal) Syncope

This type of syncope most often occurs in adolescents and young adults and is especially common in individuals with some emotional lability. There is usually some provoking stimulus, such as severe pain, apprehension of pain, or sudden emotional shock. A variety of background states, such as fasting, hot overcrowded rooms, prolonged standing, and fatigue, may add to the likelihood of vasovagal syncope.

Carotid sinus syncope arises when the carotid sinus displays unusual sensitivity to normal pressure stimuli. In elderly patients, this sensitivity is probably related to atherosclerosis of the carotid sinus region. Because the carotid sinus is abnormally sensitive even to slight pressure, syncope can be caused by a tight collar or inadvertent pressure on the side of the neck. The result is direct cardiac inhibition with bradycardia and occasionally even cardiac arrest. If carotid sinus syndrome is suspected, light massage of the neck area can be performed one side at a time as a diagnostic maneuver. This procedure should be done only by an experienced clinician with electrocardiograph (ECG) monitoring and, preferably, electroencephalograph (EEG) recording, as well.

Syncope can occur after emptying a distended urinary bladder (*micturition syncope*). This syndrome is confined to men and may be the result of both vagal stimuli and orthostatic hypotension. It occurs especially after ingestion of excess fluid and alcohol.

Syncope after prolonged coughing (*tussive syncope*) is usually seen in stocky individuals with chronic lung disease. In children with asthma, tussive syncope may mimic epilepsy. Increased intrathoracic pressure may decrease cardiac output, and vagal stimuli presumably play a role. Syncope with weight lifting probably results from similar mechanisms.

Vasomotor Syncope

A mild orthostatic fall in blood pressure often occurs in normal individuals without causing symptoms. However, syncope results when vascular reflexes that maintain cerebral blood flow with upright posture are impaired. In the United States, prescribed drugs may be the most common cause, but susceptibility varies markedly from one individual to the another. The frail and elderly are particularly vulnerable to this effect. Use of phenothiazines to control agitation in elderly patients often results in hypotension, syncope, a fall, and hip fracture. Other agents frequently implicated in orthostatic hypotension include antihypertensive drugs, diuretics, arterial vasodilators, levodopa, calcium channel blockers, tricyclic antidepressants, beta-blockers, and lithium. Orthostatic hypotension may also follow prolonged standing or an illness that leads to prolonged bed rest. Conditions that cause debilitation or lower blood pressure, such as malnutrition, anemia, blood loss, or adrenal insufficiency, also predispose to orthostatic hypotension.

Finally, several diseases of the central nervous system (CNS) or peripheral nervous system lead to failure of the vasomotor reflexes that are normally activated by standing, and may cause orthostatic hypotension. These conditions include peripheral neuropathy, especially diabetic peripheral neuropathy; diseases that affect the lateral columns of the spinal cord, such as syringomyelia; and multiple system atrophy, including the Shy-Drager syndrome.

Cardiac Syncope

Cardiac arrhythmias occur at all ages, but they are particularly frequent in the elderly. Attacks can be produced by many types of cardiac disease, and both tachyarrhythmias and bradyarrhythmias can produce syncope. The most commonly diagnosed arrhythmias are atrioventricular and sinoatrial block, and paroxysmal supra- and infraventricular tachyarrhythmias. When cardiac arrhythmia is suspected, a chest x-ray and routine ECG should first be obtained. Frequently, however, the resting ECG is normal, and thus longer periods of recording are then necessary. Minor and clinically insignificant disturbances in heart rhythm are common under such circumstances, and firm diagnosis requires concurrence of typical syncopal symptoms with a recorded arrhythmia. For a select group of patients, exercise testing and intracardiac electrophysiologic recordings may be necessary for diagnosis. Invasive electrophysiologic testing is also usually necessary when the conduction disturbance must be localized precisely. Other cardiac conditions that can cause syncope include a failing myocardium from cardiomyopathy or multiple infarctions, aortic and mitral stenosis, myxoma, congenital heart diseases, and pulmonary stenosis or emboli. Clues to a cardiac origin for syncope include attacks with little relation to posture, position, or specific triggers, as well as frequent "presyncopal" symptoms. Patients are often aware of a chest sensation that is difficult to describe. Syncope after exertion is typical of outflow obstruction. Finally, although cardiac syncope is usually of rapid onset, some tachyarrhythmias produce prolonged premonitory symptoms. Diagnosis of a cardiac cause of syncope is especially important because the 5-year mortality rate can exceed 50% in this group of patients.

Treatment

Treatment must be based on accurate diagnosis of the underlying cause of syncope. Isolated syncopal episodes require no treatment other than reassurance. Refractory vasovagal syncope, confirmed by tilt-table testing, responds best to beta-blockers, which suppress overactive cardiac mechanoreceptors. Disopyramide phosphate (Norpace), an antiarrhythmic drug, may be an alternative for some patients. Anticholinergic drugs may be effective but are poorly tolerated, especially by the elderly. In patients with orthostatic hypotension and autonomic insufficiency, initial measures should expand the intravascular volume by increasing fluid and salt intake. Fludrocortisone acetate (Florinef Acetate) is a mineralocorticoid that can be a useful adjunct in volume expansion. It must be used with caution in patients at risk for congestive heart failure. Compression stockings or other support garments may be required in more severe cases.

Differential Diagnosis

Episodic vertigo is a sudden violent sensation of movement, either of the self or the environment. The patient may interpret this as loss of consciousness. The diagnostic problem is complicated by prominent autonomic symptoms, such as sweating, nausea, and, occasionally, light-headedness, that frequently accompany vertiginous episodes. The critical element is the intensity of the vertigo.

Occasionally, transient loss of tone in the legs (e.g., in atonic seizures or with "drop attacks") may be mistaken for syncope.

Transient ischemic attacks (TIAs) due to severe atherosclerotic disease of the vertebrobasilar system are a rare cause of loss of consciousness. Episodic ischemia of the reticular formation of the brainstem is the presumptive cause. Vertebrobasilar TIAs causing loss of consciousness usually occur in patients who at other times have additional manifestations of brainstem, cerebellar, or occipital lobe dysfunction (i.e., cranial nerve palsies, Babinski sign, ataxia, hemianopia, or cortical blindness).

Hypoglycemia may cause feelings of faintness or dizziness, but only rarely with rapid loss of consciousness and rapid recovery. Characteristic of hypoglycemia are states of impaired consciousness of varying degrees and altered behavior of insidious onset. Symptoms last from minutes to hours, and if the hypoglycemia is prolonged or severe, generalized tonic-clonic seizures usually occur. Diagnosis depends on documenting profound hypoglycemia with the symptoms and reversing them by intravenous injection of glucose. Borderline or mild degrees of hypoglycemia do not cause CNS dysfunction.

SEIZURES AND EPILEPSY

Many nonepileptic events may be mistaken for seizures, depending on patient age, the nature of the symptoms, and the circumstances of the attacks ([Table 3.4](#)). Syncope has been reviewed in the foregoing section, but additional points may be pertinent. Epileptic seizures, unlike syncope, are never consistently related to head or body posture. In complex partial seizures, impaired or lost consciousness is usually accompanied by automatisms or other involuntary movements. Falls are unusual, unless the seizure becomes generalized. Urinary incontinence and postictal confusion or lethargy are common with seizures; both are rare with syncope.

photophobia.

Transient Ischemic Attack

TIA's are not usually confused with seizures. Diagnosis is occasionally difficult when a TIA is apparent only by dysphasia or disturbed sensation over part or all of one side of the body, or when muscle weakness results in a fall. In general, focal sensory symptoms associated with epilepsy show sequential spread from one body area to another, whereas ischemic paresthesias lack this segmental spread, instead developing simultaneously over affected areas. Absence of clonic motor activity and confusion favor focal ischemia more than epilepsy. Furthermore, the "negative" nature of the predominant symptoms generally argue against epilepsy.

[Coma from Metabolic or Diffuse Brain Disease](#)
[Hysteria and Catatonia](#)
[Locked-In Syndrome](#)
[Vegetative State](#)
[Brain Death](#)
[Suggested Readings](#)

Consciousness, the awareness of self and environment, requires both arousal and mental content; the anatomic substrate includes both reticular activating system and cerebral cortex. Coma is a state of unconsciousness that differs from syncope in being sustained and from sleep in being less easily reversed. Cerebral oxygen uptake (cerebral metabolic rate of oxygen [CMRO₂]) is normal in sleep or actually increases during the rapid eye movement stage, but CMRO₂ is abnormally reduced in coma.

Coma is clinically defined by the neurologic examination, especially responses to external stimuli. Terms such as *lethargy*, *obtundation*, *stupor*, and coma usually depend on the patient's response to normal verbal stimuli, shouting, shaking, or pain. These terms are not rigidly defined, and it is useful to record both the response and the stimulus that elicited it. Occasionally, the true level of consciousness may be difficult or impossible to determine (e.g., when there is catatonia, severe depression, curarization, or akinesia plus aphasia).

Confusional state and *delirium* are terms that refer to a state of inattentiveness, altered mental content, and, sometimes, hyperactivity rather than to a decreased level of arousal; these conditions may presage or alternate with obtundation, stupor, or coma.

EXAMINATION AND MAJOR DIAGNOSTIC PROCEDURES

In the assessment of a comatose patient, it is first necessary to detect and treat any immediately life-threatening condition: Hemorrhage is stopped; the airway is protected, with intubation when necessary (including the prevention of aspiration in a patient who is vomiting); circulation is supported; and an electrocardiogram is obtained to detect dangerous arrhythmia. If the diagnosis is unknown, blood is drawn for glucose determination, after which 50% dextrose is given intravenously with parenteral thiamine. (Administering glucose alone to a thiamine-deficient patient may precipitate Wernicke-Korsakoff syndrome.) When opiate overdose is a possibility, naloxone hydrochloride (Narcan) is given. If trauma is suspected, damage to internal organs and fracture of the neck should be taken into consideration until radiographs determine otherwise.

The next step is to ascertain the site and cause of the lesion. The history is obtained from whoever accompanies the patient, including ambulance drivers and police. Examination should include the following: skin, nails, and mucous membranes (for pallor, cherry redness, cyanosis, jaundice, sweating, uremic frost, myxedema, hypo- or hyperpigmentation, petechiae, dehydration, decubiti, or signs of trauma); the breath (for acetone, alcohol, or fetor hepaticus); and the fundi (for papilledema, hypertensive or diabetic retinopathy, retinal ischemia, Roth spots, granulomas, or subhyaloid hemorrhages). Fever may imply infection or heat stroke; hypothermia may occur with cold exposure (especially in alcoholics), hypothyroidism, hypoglycemia, sepsis, or, infrequently, a primary brain lesion. Asymmetry of pulses may suggest dissecting aneurysm. Urinary or fecal incontinence may signify an unwitnessed seizure, especially in patients who awaken spontaneously. The scalp should be inspected and palpated for signs of trauma (e.g., Battle sign), and the ears and nose are examined for blood or cerebrospinal fluid (CSF). Resistance to passive neck flexion but not to turning or tilting suggests meningitis, subarachnoid hemorrhage, or foramen magnum herniation, but may be absent early in the course of the disorder and in patients who are deeply comatose. Resistance in all directions suggests bone or joint disease, including fracture.

In their classic monograph, Plum and Posner (1980) divided the causes of coma into supra- and infratentorial structural lesions and diffuse or metabolic diseases. By concentrating on motor responses to stimuli, respiratory patterns, pupils, and eye movements, the clinician can usually identify the category of coma.

The patient is observed to assess respiration, limb position, and spontaneous movements. Myoclonus or seizures may be subtle (e.g., twitching of one or two fingers or the corner of the mouth). More florid movements, such as facial grimacing, jaw gyrations, tongue protrusion, or complex repetitive limb movements, may defy ready interpretation. Asymmetric movements or postures may signify either focal seizures or hemiparesis.

Asymmetry of muscle tone suggests a structural lesion, but it is not always clear which side is abnormal. *Gegenhalten*, or *paratonia*, is resistance to passive movement that, in contrast to parkinsonian rigidity, increases with the velocity of the movement and, unlike clasp-knife spasticity, continues through the full range of the movement; it is attributed to diffuse forebrain dysfunction and is often accompanied by a grasp reflex.

Motor responses to stimuli may be appropriate, inappropriate, or absent. Even when patients are not fully awake, they may be roused to follow simple commands. Some patients who respond only to noxious stimuli (e.g., pressure on the sternum or supraorbital bone, pinching the neck or limbs, or squeezing muscle, tendon, or nailbeds) may make voluntary avoidance responses. The terms "decorticate" and "decerebrate" posturing are physiologic misnomers but refer to hypertonic flexion or extension in response to noxious stimuli. In *decorticate rigidity*, the arms are flexed, adducted, and internally rotated, and the legs are extended; in *decerebrate rigidity*, the arms and legs are all extended. These postures are most often associated with cerebral hemisphere disease, including metabolic encephalopathy, but may follow upper brainstem lesions or transtentorial herniation.

Flexor postures generally imply a more rostral lesion and have a better prognosis than extensor posturing, but the pattern of response may vary with different stimuli, or there may be flexion of one arm and extension of the other. When these postures seem to occur spontaneously, there may be an unrecognized stimulus (e.g., airway obstruction or bladder distention). With continuing rostrocaudal deterioration, there may be extension of the arms and flexion of the legs until, with lower brainstem destruction, there is flaccid unresponsiveness. However, lack of motor response to any stimulus should always raise the possibility of limb paralysis caused by cervical trauma, Guillain-Barré neuropathy, or the locked-in state.

Respiration

In Cheyne-Stokes respiration (CSR), periods of hyperventilation and apnea alternate in a crescendo-decrescendo fashion. The hyperpneic phase is usually longer than the apneic, so that arterial gases tend to show respiratory alkalosis; during periods of apnea, there may be decreased responsiveness, miosis, and reduced muscle tone. CSR occurs with bilateral cerebral disease, including impending transtentorial herniation, upper brainstem lesions, and metabolic encephalopathy. It usually signifies that the patient is not in imminent danger. Conversely, "short-cycle CSR" (*cluster breathing*) with less smooth waxing and waning is often an ominous sign of a posterior fossa lesion or dangerously elevated intracranial pressure.

Sustained hyperventilation is usually due to metabolic acidosis, pulmonary congestion, hepatic encephalopathy, or stimulation by analgesic drugs ([Fig. 4.1](#)). Rarely, it is the result of a lesion in the rostral brainstem. *Apneustic breathing*, consisting of inspiratory pauses, is seen with pontine lesions, especially infarction; it occurs infrequently with metabolic coma or transtentorial herniation.

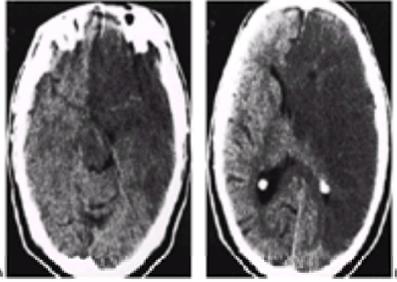

FIG. 4.1. Cerebral herniation secondary to hemispherical infarction. Noncontrast axial CT demonstrates an extensive area of decreased density within the left frontal, temporal, and parietal lobes with relative sparing of the left thalamus and left occipital lobe. A dense left middle cerebral artery is seen, consistent with thrombosis. **A:** Obliteration of the suprasellar cistern by the medial left temporal lobe indicates uncal herniation. **B:** Left-to-right shift of the left frontal lobe, left caudate nucleus, and left internal capsule denote severe subfalcine herniation. (Courtesy of Dr. S. Chan, Columbia University College of Physicians and Surgeons, New York, N.Y.)

Respiration having a variably irregular rate and amplitude (*ataxic* or *Biot breathing*) indicates medullary damage and can progress to apnea, which also occurs abruptly in acute posterior fossa lesions. Loss of automatic respiration with preserved voluntary breathing (*Ondine curse*) occurs with medullary lesions; as the patient becomes less alert, apnea can be fatal. Other ominous respiratory signs are end-expiratory pushing (e.g., coughing) and “fish-mouthing” (i.e., lower-jaw depression with inspiration). Stertorous breathing (i.e., inspiratory noise) is a sign of airway obstruction.

Pupils

Pupillary abnormalities in coma may reflect an imbalance between input from the parasympathetic and sympathetic nervous systems or lesions of both. Although many people have slight pupillary inequality, anisocoria should be considered pathologic in a comatose patient. Retinal or optic nerve damage does not cause anisocoria, even though there is an afferent pupillary defect. Parasympathetic lesions (e.g., oculomotor nerve compression in uncal herniation or after rupture of an internal carotid artery aneurysm) cause pupillary enlargement and ultimately full dilatation with loss of reactivity to light. Sympathetic lesions, either intraparenchymal (e.g., hypothalamic injury or lateral medullary infarction) or extraparenchymal (e.g., invasion of the superior cervical ganglion by lung cancer), cause Horner syndrome with miosis. With involvement of both systems (e.g., midbrain destruction), one or both pupils are in midposition and are unreactive. Pinpoint but reactive pupils following pontine hemorrhage are probably the result of damage to descending intraaxial sympathetic pathways, as well as to a region of the reticular formation that normally inhibits the Edinger-Westphal nucleus.

With few exceptions, metabolic disease does not cause unequal or unreactive pupils. Fixed, dilated pupils after diffuse anoxia-ischemia carry a bad prognosis. Anticholinergic drugs, including glutethimide, amitriptyline, and antiparkinsonian agents, abolish pupillary reactivity. Hypothermia and severe barbiturate intoxication can cause not only fixed pupils but a reversible picture that mimics brain death. Bilateral or unilateral pupillary dilatation and unreactivity can accompany (or briefly follow) a seizure. In opiate overdose, miosis may be so severe that a very bright light and a magnifying glass are necessary to detect reactivity. Some pupillary abnormalities are local in origin (e.g., trauma or synechiae).

Eyelids and Eye Movements

Closed eyelids in a comatose patient mean that the lower pons is intact, and blinking means that reticular activity is taking place; however, blinking can occur with or without purposeful limb movements. Eyes that are conjugately deviated away from hemiparetic limbs indicate a destructive cerebral lesion on the side toward which the eyes are directed. Eyes turned toward paretic limbs may mean a pontine lesion, an adverse seizure, or the wrong-way gaze paresis of thalamic hemorrhage. Eyes that are dysconjugate while at rest may mean paresis of individual muscles, internuclear ophthalmoplegia, or preexisting tropia or phoria.

When the brainstem is intact, the eyes may rove irregularly from side to side with a slow, smooth velocity; jerky movements suggest saccades and relative wakefulness. Repetitive smooth excursions of the eyes first to one side and then to the other, with 2- to 3-second pauses in each direction (*periodic alternating* or *ping-pong gaze*), may follow bilateral cerebral infarction or cerebellar hemorrhage with an intact brainstem.

If cervical injury has been ruled out, oculocephalic testing (the *doll's-eye maneuver*) is performed by passively turning the head from side to side; with an intact reflex arc (vestibular–brainstem–eye muscles), the eyes move conjugately in the opposite direction. A more vigorous stimulus is produced by irrigating each ear with 30 to 100 mL of ice water. A normal awake person with head elevated 30 degrees has nystagmus with the fast component in the direction opposite the ear stimulated, but a comatose patient with an intact reflex arc has deviation of the eyes toward the stimulus, usually for several minutes. Simultaneous bilateral irrigation causes vertical deviation, upward after warm water and downward after cold water.

Oculocephalic or caloric testing may reveal intact eye movements, gaze palsy, individual muscle paresis, internuclear ophthalmoplegia, or no response. Cerebral gaze paresis can often be overcome by these maneuvers, but brainstem gaze palsies are usually fixed. Complete ophthalmoplegia may follow either extensive brainstem damage or metabolic coma, but except for barbiturate or phenytoin sodium (Dilantin) poisoning, eye movements are preserved early in metabolic encephalopathy. Unexplained dysconjugate eyes indicate a brainstem or cranial nerve lesion (including abducens palsy due to increased intracranial pressure).

Downward deviation of the eyes occurs with lesions in the thalamus or midbrain pretectum and may be accompanied by pupils that do not react to light (*Parinaud syndrome*). Downward eye deviation also occurs in metabolic coma, especially in barbiturate poisoning, and after a seizure. Skew deviation, or vertical divergence, follows lesions of the cerebellum or brainstem, especially the pontine tegmentum.

Retraction and convergence nystagmus may be seen with midbrain lesions, but spontaneous nystagmus is rare in coma. *Ocular bobbing* (conjugate brisk downward movements from the primary position) usually follows destructive lesions of the pontine tegmentum (when lateral eye movements are lost) but may occur with cerebellar hemorrhage, metabolic encephalopathy, or transtentorial herniation. Unilateral bobbing (nystagmoid jerking) signifies pontine disease.

Tests

Computed tomography (CT) or magnetic resonance imaging (MRI) is promptly performed whenever coma is unexplained. Unless meningitis is suspected and the patient is clinically deteriorating, imaging should precede lumbar puncture. If imaging is not readily available, a spinal tap is cautiously performed with a no.20 or no.22 needle. If imaging reveals frank transtentorial or foramen magnum herniation, the comparative risks of performing a lumbar puncture or of treating for meningitis without CSF confirmation must be weighed individually for each patient.

Other emergency laboratory studies include blood levels of glucose, sodium, calcium, and blood urea nitrogen (or creatinine); determination of arterial pH and partial pressures of oxygen and carbon dioxide; and blood or urine toxicology testing (including blood levels of sedative drugs and ethanol). Blood and CSF should be cultured, and liver function studies and other blood electrolyte levels determined. Coagulation studies and other metabolic tests are based on index of suspicion.

The electroencephalogram (EEG) can distinguish coma from psychic unresponsiveness or locked-in state, although alpha-like activity in coma after brainstem infarction or cardiopulmonary arrest may make the distinction difficult. In metabolic coma, the EEG is always abnormal, and early in the course, it may be a more sensitive indicator of abnormality than the clinical state of the patient. The EEG may also reveal asymmetries or evidence of clinically unsuspected seizure activity. Infrequently, patients without clinical seizures demonstrate repetitive electrographic seizures or continuous spike-and-wave activity; conversely, patients with subtle motor manifestations of seizures sometimes display only diffuse electrographic slowing. Distinguishing true status epilepticus from myoclonus (common after anoxic-ischemic brain damage) is often difficult, both clinically and electrographically; and if any doubt exists, anticonvulsant therapy should be instituted.

COMA FROM SUPRATENTORIAL STRUCTURAL LESIONS

and respiration. At first glance, the patient appears unresponsive, but examination reveals voluntary vertical and sometimes horizontal eye movements, including blinking. (Even with facial paralysis, inhibition of the levator palpebrae can produce partial eye closure.) Communication is possible with blinking or eye movements to indicate “yes,” “no,” or letters.

VEGETATIVE STATE

The terms *akinetic mutism* and *coma vigili* have been used to describe a variety of states, including coma with preserved eye movements following midbrain lesions, psychomotor bradykinesia with frontal lobe disease, and isolated diencephalic and brainstem function after massive cerebral damage. For this last condition, the term *vegetative state* is preferred to refer to patients with sleep–wake cycles, intact cardiorespiratory function, and primitive responses to stimuli, but without evidence of inner or outer awareness (Table 4.3). Patients who survive coma usually show varying degrees of recovery within 2 to 4 weeks; those who enter the vegetative state may recover further, even fully. *Persistent vegetative state* is defined as a vegetative state present for at least 1 month. Although further improvement is then unlikely, anecdotal reports exist of recovery after many months. The technologic feasibility of indefinitely prolonging life without consciousness has generated considerable ethical debate.

-
1. No evidence of awareness of self or surroundings. Reflex or spontaneous eye opening may occur.
 2. No communication between examiner and patient, auditory or written, that is meaningful and consistent. Target stimuli not usually followed visually, but sometimes visual tracking present. No emotional response to verbal stimuli.
 3. No comprehensible speech or mouthing of words.
 4. Smiling, frowning, or crying inconsistently related to any apparent stimulus.
 5. Sleep–wake cycles present.
 6. Brainstem and spinal reflexes variable, e.g., preservation of sucking, rooting, chewing, swallowing, pupillary reactivity to light, oculocephalic responses, and grasp or tendon reflexes.
 7. No voluntary movements or behavior, no matter how rudimentary; no motor activity suggesting learned behavior; no mimicry. Withdrawal or posturing can occur with noxious stimuli.
 8. Usually intact blood pressure control and cardiorespiratory function. Incontinence of bladder and bowel.
-

TABLE 4.3. CRITERIA FOR DETERMINATION OF VEGETATIVE STATE

BRAIN DEATH

Unlike vegetative state, in which the brainstem is intact, the term *brain death* means that neither the cerebrum nor the brainstem is functioning. The only spontaneous activity is cardiovascular, apnea persists in the presence of hypercarbia sufficient for respiratory drive, and the only reflexes present are those mediated by the spinal cord (Table 4.4). In adults, brain death rarely lasts more than a few days and is always followed by circulatory collapse. In the United States, brain death is equated with legal death. When criteria are met, artificial ventilation and blood pressure support are appropriately discontinued, whether or not organ harvesting is intended.

-
1. Coma, unresponsive to stimuli above foramen magnum.
 2. Apnea off ventilator (with oxygenation) for a duration sufficient to produce hypercarbic respiratory drive (usually 10–20 minutes to achieve P_{aCO_2} of 50–60 mm Hg).
 3. Absence of cephalic reflexes, including pupillary, oculocephalic, oculovestibular (caloric), corneal, gag, sucking, swallowing, and extensor posturing. Purely spinal reflexes may be present, including tendon reflexes, plantar responses, and limb flexion to noxious stimuli.
 4. Body temperature above 34°C.
 5. Systemic circulation may be intact.
 6. Diagnosis known to be structural disease or irreversible metabolic disturbance; absence of drug intoxication, including ethanol, sedatives, potentially anesthetic agents, or paralyzing drugs.
 7. In adults with known structural cause and without improvement of drug or ethanol, at least 6 hours of absent brain function for asphyxia, including those with anoxic-ischemic brain damage, at least 24 hours' observation plus negative drug screen.
 8. Diagnosis of brain death inappropriate in infants younger than 7 days. Observation of at least 48 hours for infants aged 7 days to 2 months, at least 24 hours for those aged 2 months to 1 year, and at least 12 hours for those aged 1–5 years (24 hours if anoxic-ischemic brain damage). For older children, adult criteria apply.
 9. Optional confirmatory studies include:
 EEG isoelectric for 30 minutes at maximal gain
 Absent brainstem evoked responses
 Absent cerebral circulation demonstrated by radiographic, radionuclide, or magnetic resonance angiography.

CHAPTER 5. DIAGNOSIS OF PAIN AND PARESTHESIAS

LEWIS P. ROWLAND

[Neck Pain](#)
[Low Back Pain](#)
[Arm Pain](#)
[Leg Pain and Paresthesias](#)
[Suggested Readings](#)

All pain sensations are carried by nerves and therefore concern neurology; however, not all pain is relevant to neurologic diagnosis. The pain of any traumatic lesion is a separate concern. Except for attacks of herpes zoster or diabetic radiculopathy, pain in the thorax or abdomen almost always implies a visceral disorder rather than one of the spinal cord or nerve roots. Headache and other head pains, in contrast, are a major neurologic concern (see [Chapter 8](#)) and [Chapter 139](#)). This chapter considers pain in the neck, low back, and limbs.

Pain syndromes often include another sensory aberration, *paresthesia*, a spontaneous and abnormal sensation. The problem may arise from an abnormality anywhere along the sensory pathway from the peripheral nerves to the sensory cortex. A paresthesia is often described as a *pins-and-needles sensation* and is recognizable by anyone who has ever had an injection of local anesthetic for dental repairs. Central nervous system disorders may cause particular kinds of paresthesias: focal sensory seizures with cortical lesions, spontaneous pain in the thalamic syndrome, or bursts of paresthesias down the back or into the arms on flexing the neck (*Lhermitte symptoms*) in patients with multiple sclerosis or other disorders of the cervical spinal cord. Level lesions of the spinal cord may cause either a band sensation or a girdle sensation, a vague sense of awareness of altered sensation encircling the abdomen, or there may be a *sensory level* (i.e., altered sensation below the level of the spinal cord lesion). Nerve root lesions or isolated peripheral nerve lesions may also cause paresthesias, but the most intense and annoying paresthesia encountered is due to multiple symmetric peripheral neuropathy (polyneuropathy). *Dysesthesia* is the term for the disagreeably abnormal sensations evoked when an area of abnormal sensation is touched; sometimes even the pressure of bedclothes cannot be tolerated by a patient with dysesthesia.

Beginning students are often confused by reports of paresthesias when the review of systems is recorded, or when they find abnormalities in the sensory examination that do not conform to normal anatomic patterns. Two general rules may help:

1. If paresthesias do not persist, they are likely to imply a neurologic lesion. (Pressure on a nerve commonly causes transient paresthesias in normal people who cross their legs, sit too long on a toilet seat, drape an arm over the back of a chair, or lean on one elbow while holding a newspaper in that hand. Many people have fleeting paresthesias of unknown cause and no significance.)
2. If paresthesias persist and the examiner fails to find a corresponding abnormality to explain it, the patient should be reexamined. Persistent paresthesias reliably imply an abnormality of sensory pathways.

NECK PAIN

Most chronic neck pain is caused by bony abnormalities (cervical osteoarthritis or other forms of arthritis) or by local trauma. If pain remains local (i.e., not radiating into the arms), it is rarely of neurologic significance unless there are abnormal neurologic signs. It may be possible to demonstrate overactive tendon reflexes, clonus, or Babinski signs in a patient who has no symptoms other than neck pain. These signs could be evidence of compression of the cervical spinal cord and might be an indication for cervical magnetic resonance imaging (MRI) or myelography to determine whether the offending lesion is some form of arthritis, tumor, or a congenital malformation of the cervical spine; however, neck pain is rarely encountered as the only symptom of a compressive lesion.

Neck pain of neurologic significance is more commonly accompanied by other symptoms and signs, depending on the location of the lesion: *Radicular* distribution of pain is denoted by radiation down the medial (ulnar) or lateral (radial) aspect of the arm, sometimes down to the corresponding fingers. Cutaneous sensation is altered within the area innervated by the compromised root, or below the level of spinal end compression. The motor disorder may be evident by weakness and wasting of hand muscles innervated by the affected root, and the gait may be abnormal if there are corticospinal signs of cervical spinal cord compression. When autonomic fibers in the spinal cord are compromised, abnormal urinary frequency, urgency, or incontinence may occur, there may be bowel symptoms, and men may note sexual dysfunction. Reflex changes may be noted by the loss of tendon reflexes in the arms and overactive reflexes in the legs. Cervical pain of neurologic significance may be affected by movement of the head and neck, and it may be exaggerated by natural Valsalva maneuvers in coughing, sneezing, or straining during bowel movements.

Cervical spondylosis is a more common cause of neck pain than is spinal cord tumor, but it is probably not possible to make the diagnostic distinction without MRI or myelography because the pain may be similar in the two conditions. In young patients (i.e., younger than 40 years), tumors, spinal arteriovenous malformations, and congenital anomalies of the cervicooccipital region are more common causes of neck pain than cervical spondylosis.

LOW BACK PAIN

The most common cause of low back pain is herniated nucleus pulposus, but it is difficult to determine the exact frequency because acute attacks usually clear spontaneously and chronic low back pain is colored by psychologic factors. The pain of an acute herniation of a lumbar disc is characteristically abrupt in onset and brought on by heavy lifting, twisting, or Valsalva maneuvers (sneezing, coughing, or straining during bowel movements). The patient may not be able to stand erect because paraspinal muscles contract so vigorously, yet the pain may be relieved as soon as the patient lies down, only to return again on any attempt to stand. The pain may be restricted to the low back or may radiate into one or both buttocks or down the posterior aspect of the leg to the thigh, knee, or foot. The distribution of pain sometimes gives a precise delineation of the nerve root involved, but this is probably true in only a minority of cases. The pain of an acute lumbar disc herniation is so stereotyped that the diagnosis can be made even if there are no reflex, motor, or sensory changes.

Chronic low back pain is a different matter. If neurologic abnormalities are present on examination, MRI or myelography is often indicated to determine whether the problem is caused by tumor, lumbar spondylosis with or without spinal stenosis, or arachnoiditis. If there are no neurologic abnormalities or if the patient has already had a laminectomy, chronic low back pain may pose a diagnostic and therapeutic dilemma. This major public health problem accounts for many of the patients who enroll in pain clinics.

ARM PAIN

Pain in the arms takes on a different significance when there is no neck pain. Local pain arises from musculoskeletal diseases (e.g., bursitis or arthritis), which are now common because of widespread participation in sports by people who are not properly prepared.

Chronic pain may arise from invasion of the brachial plexus by tumors that extend directly from lung or breast tissue or that metastasize from more remote areas. The brachial plexus may also be affected by a transient illness (e.g., *brachial plexus neuritis*) that includes pain in the arm that is often poorly localized. The combination of pain, weakness, and wasting has given rise to the name *neuralgic amyotrophy*. (Amyotrophy is taken from Greek words meaning loss of nourishment to muscles; in practice, it implies the wasting of muscle that follows denervation.)

Thoracic outlet syndromes are another cause of arm pain that originates in the brachial plexus. The pain of a true thoracic outlet syndrome is usually brought on by particular positions of the arm and is a cause of diagnostic vexation because there may be no abnormality on examination (see [Chapter 69](#)). In a true thoracic outlet syndrome, the neurologic problems are often caused by compressed and distended blood vessels that in turn secondarily compress nerves or lead to ischemia of nerves.

Single nerves may be involved in *entrapment neuropathies* that cause pain in the hands. Carpal tunnel syndrome of the median nerve is the best known entrapment neuropathy. The ulnar nerve is most commonly affected at the elbow but may be subject to compression at the wrist. The paresthesias of entrapment neuropathies are restricted to the distribution of the affected nerve and differ from the paresthesias of areas innervated by nerve roots, although the distinction may be difficult to make

if only a portion of the area supplied by a particular nerve root is affected.

Causalgia (see [Chapter 70](#)) is the name given to a constant burning pain accompanied by trophic changes that include red glossy skin, sweating in the affected area, and abnormalities of hair and nails. The trophic changes are attributed to an autonomic disorder. Causalgia was described in the 19th century in a monograph by Mitchell, Morehouse, and Keen when they reviewed gunshot wounds and other nerve injuries of American Civil War veterans. The basic mechanisms of causalgia are still poorly understood. The traumatic lesions of peripheral nerves are usually incomplete, and several nerves are often involved simultaneously. Causalgia usually follows high-velocity missile wound (bullets or shrapnel). It is less commonly caused by traction injury and is only rarely seen in inflammatory neuropathy or other types of peripheral nerve disease. The arms are more often involved than the legs, and the lesions are usually above the elbow or below the knee. Symptoms usually begin within the first few days following injury. Causalgic pain most often involves the hand. The shiny red skin, accompanied by fixed joints, is followed by osteoporosis. Both physical and emotional factors seem to play a role. Causalgia may be relieved by sympathectomy early in the course of treatment and may be due to *ephaptic transmission* through connections between efferent autonomic fibers at the site of partial nerve injury. This concept of “artificial synapses” after nerve injury has been widely accepted; however, there has been no convincing anatomic or physiologic corroboration.

Reflex sympathetic dystrophy refers to local tissue swelling and bony changes that accompany causalgia. Similar changes may be encountered after minor trauma or arthritis of the wrist. In the shoulder–hand syndrome, inflammatory arthritis of the shoulder joint may be followed by painful swelling of the hand, with local vascular changes, disuse, and atrophy of muscle and bone. Sympathectomy has been recommended.

A major problem in the management of causalgic syndromes is the lack of properly controlled comparison of placebo with sympathetic blockade, as well as the difficulty in evaluating psychogenic factors and the confusion caused by incomplete syndromes (with or without preceding trauma, with or without attendant vascular abnormalities, and with or without response to sympathetic block).

LEG PAIN AND PARESTHESIAS

Leg pain due to occlusive vascular disease, especially with diabetes, varies markedly in different series but seems to be related to the duration of the diabetes and shows increasing incidence with age. Pain may be a major symptom of diabetic peripheral neuropathy of the multiple symmetric type. Diabetic mononeuritis multiplex, attributed to infarcts of the lumbosacral plexus or a peripheral nerve, is a cause of more restricted pain, usually of abrupt onset. Diabetic mononeuropathy may be disabling and alarming at the onset, but both pain and motor findings improve in a few months to 1 or 2 years. Nutritional neuropathy is an important cause of limb pain, especially in the legs, in some parts of the world. This condition was striking in prisoner-of-war camps in World War II and has also been noted in patients on hemodialysis. Sudden fluid shifts may cause peripheral nerve disease symptoms for a time after dialysis.

Barring intraspinal disease, the most common neurologic cause of leg pain and paresthesias is probably multiple symmetric peripheral neuropathy. The paresthesias usually take on a glove-and-stocking distribution, presumably because the nerve fibers most remote from the perikaryon are most vulnerable. The feet are usually affected, sometimes alone or sometimes with the hands; the hands are rarely affected alone. Mixed sensorimotor neuropathies show motor abnormalities with weakness and wasting, as well as loss of tendon reflexes. Some neuropathies are purely sensory. Pain is characteristic of severe diabetic neuropathy, alcoholic neuropathy, amyloid neuropathy, and some carcinomatous neuropathies, but it is uncommon in inherited neuropathies or the Guillain-Barré syndrome. The pain of peripheral neuropathy, for unknown reasons, is likely to be more severe at night.

Entrapment neuropathy rarely affects the legs; however, diabetic mononeuropathy, especially femoral neuropathy, may cause pain of restricted distribution and abrupt onset, with later improvement of the condition that may take months.

Another major cause of leg pain is invasion of the lumbosacral plexus by tumor, but this is rarely an isolated event and other signs of the tumor are usually evident. The problem of distinguishing between spinal and vascular claudication is discussed in [Chapter 67](#).

Limb pain and paresthesias are important in neurologic diagnosis not only because they persist for prolonged periods. They also become the object of symptomatic therapy by analgesics, tricyclic antidepressant drugs, and monoamine oxidase inhibitors (which may affect abnormal sensations by actions other than antidepressant effects), transcutaneous nerve stimulation, dorsal column stimulation, cordotomy, acupuncture, and other procedures. The long list of remedies attests to the limitations of each. Psychologic factors cannot be ignored in chronic pain problems.

CHAPTER 6. DIZZINESS AND HEARING LOSS

JACK J. WAZEN

[Tinnitus](#)
[Hearing Loss](#)
[Dizziness](#)
[Common Causes of Dizziness and Hearing Loss](#)
[Taking the History](#)
[Conclusion](#)
[Suggested Readings](#)

The peripheral auditory system is composed of the outer ear, the middle ear, the inner ear (cochlea and vestibular system), and the eighth cranial nerve. Lesions of these structures cause three major symptoms: hearing loss, vertigo, and tinnitus. Vertigo usually implies a lesion of the inner ear or the vestibular portion of the eighth nerve. Tinnitus and hearing loss may arise from lesions anywhere in the peripheral or central auditory pathways.

TINNITUS

Tinnitus is an auditory sensation that arises within the head and is perceived in one or both ears, or inside the head. The sound may be continuous, intermittent, or pulsatile. Tinnitus should be divided into *objective tinnitus*, heard by the examiner as well as the patient, or *subjective tinnitus*, heard only by the patient. Objective tinnitus is uncommon, but it is associated with several serious conditions that mandate early diagnosis.

Objective Tinnitus

This condition results from intravascular turbulence, increased blood flow, or movement in the eustachian tube, soft palate, or temporomandibular joint. Bruits due to vascular turbulence may arise from aortic stenosis, carotid stenosis, arteriovenous malformations of the head and neck, vascular tumors (e.g., glomus jugulare), or aneurysms of the abdomen, chest, head, or neck. A continuous hum may result from asymmetric enlargement of the sigmoid sinus and the jugular vein. Pulsatile objective tinnitus may result from high blood pressure, hyperthyroidism, or increased intracranial pressure. As part of the diagnostic evaluation of objective tinnitus, the stethoscope should be used for auscultation of the ear, head, and neck in all patients who note noises in the head or ear. Anyone with pulsatile tinnitus should also have blood pressure and fundoscopic evaluation.

Subjective Tinnitus

Unless of brief duration, subjective tinnitus results from damage or abnormality somewhere in the auditory system. The abnormality can be in the external ear, middle ear, inner ear, eighth cranial nerve, or central auditory connections. Tinnitus may be an early warning signal, such as pain arising from a lesion in or near a sensory peripheral nerve. For example, tinnitus after exposure to loud noise is due to cochlear injury, usually resulting in a temporary shift of the threshold in hearing sensitivity. Repeated exposure to noise may result in permanent cochlear damage and permanent hearing loss. Unilateral tinnitus is an early symptom of acoustic neuroma, often years before there is overt loss of hearing or unsteadiness of gait. Persistent tinnitus therefore requires otologic evaluation, including hearing tests. The basic hearing tests for evaluation of patients with tinnitus comprise pure tone and speech audiometry, as well as middle ear impedance measures, including tympanometry and measurement of the threshold and decay of the stapedial reflex. Auditory evoked potentials are often necessary, even in the absence of a significant difference in the hearing thresholds. Auditory evoked potentials, however, do not replace conventional audiometry and must be interpreted in light of the audiogram. These tests help localized the site of the lesion.

HEARING LOSS

Hearing loss can be divided into two anatomic types on the basis of the site of the lesion: conductive and sensorineural. Conductive hearing loss is due to middle ear disease. Sensorineural hearing loss is most often due to a lesion in the cochlea or the cochlear nerve. It rarely results from central auditory dysfunctions.

Conductive Hearing Loss

This type of hearing loss results from conditions in the external or middle ear that interfere with movement of the oval or round window. Patients with conductive hearing loss speak with a soft voice or with normal loudness because to them their own voices sound louder than background sounds in the environment. External ear or middle ear abnormalities are usually evident on physical examination, except when there is ossicular fixation (e.g., with otosclerosis), ossicular discontinuity from trauma, or erosion from chronic otitis media with or without cholesteatoma. In tuning-fork tests, best carried out with a 256- or 512-Hz tuning fork, sound conveyed by bone conduction is as loud as or louder than air conduction (negative Rinne test). In contrast, sound conveyed by air conduction is perceived as louder than bone conduction sound in patients with normal hearing or with sensorineural hearing loss. In conductive hearing loss, a tuning fork placed at midline of the forehead is heard louder in the ear on the side of the hearing loss (Weber test lateralizes to the abnormal side).

The diagnosis of conductive hearing loss can be confirmed by testing middle ear impedance, which measures the resistance of the middle ear to the passage of sound and can differentiate ossicular discontinuity from stiffness or mass effects that interfere with movement of the oval window. The severity of hearing loss and the conductive component should be assessed by audiometry, which determines sound conduction by air and bone. Conductive hearing loss most commonly affects children and is usually due to otitis media with effusion. Conductive hearing loss should be treated vigorously in children because persistent hearing loss, even if slight, may interfere with speech and cognitive development. Chronic forms of conductive hearing loss can usually be restored to functional levels of hearing by reconstructive microsurgery. Hearing aids are also effective in rehabilitating patients with conductive hearing loss.

Sensorineural Hearing Loss

This condition is due to defects in the cochlea, cochlear nerve, or the brainstem and cortical connections. Patients with sensorineural hearing loss tend to speak with a loud voice. Findings on physical examination are normal. Tuning-fork tests show that air conduction exceeds bone conduction (positive Rinne test); in the Weber test, the tuning fork seems louder in the better ear.

Patients with sensorineural hearing loss require a battery of audiometric tests to determine the site of the abnormality. Patients with cochlear damage may show low-frequency hearing loss, a flat audiometric configuration, or, more commonly, high-frequency hearing loss. The main causes are excessive exposure to noise, ototoxic drugs, age-related cochlear degeneration, congenital cochlear defects, and viral or bacterial infections. Speech discrimination remains relatively preserved, compared to the extent of pure-tone hearing loss. The stapedial reflex threshold, as determined by impedance measurements, is present at reduced sensation levels; that pattern implies *recruitment*, an abnormal increase in the subjective sensation of loudness as the amplitude of the test sounds increases above the threshold. Brainstem auditory evoked responses show a delay in the first brainstem wave, but a normal or shortened interpeak latency.

Patients with damage to the cochlear nerve, such as the neural form of presbycusis or compression of the nerve by an acoustic neuroma, usually show high-frequency hearing loss, as do patients with cochlear lesions. In nerve lesions, however, speech discrimination tends to be more severely affected than pure-tone hearing loss. The stapedial reflex either is absent or shows abnormal adaptation or decay. The test is carried out as part of impedance audiometry and is useful in determining the site of the lesion. Stapedial reflex threshold and decay, along with tympanometry, must be considered part of the diagnostic workup for all patients with asymmetric sensorineural hearing loss. Brainstem auditory evoked response testing in neural forms of hearing loss shows no waves at all, poorly formed waves, or normal or increased interpeak latency, either absolute or in comparison with the opposite ear.

Central lesions, such as recurrent small strokes or multiple sclerosis, often cause no detectable pure-tone hearing loss because the central auditory pathways are bilateral. Some patients, however, do note hearing loss. For them, hearing should be evaluated by brainstem auditory evoked response testing, which may show bilateral conduction delay despite normal pure-tone hearing. Central auditory testing may show abnormalities.

Most patients with sensorineural hearing loss can be helped by amplification; hearing aids are becoming smaller and more effective. The narrow range between speech and noise is being ameliorated by improved microcircuitry. The latest in hearing aid technology, including digital and programmable devices, allows individuals to change the hearing aid parameters under different acoustical conditions for better hearing, particularly in noisy backgrounds. Patients with profound bilateral sensorineural hearing loss not responding to hearing aids may be candidates for a cochlear implant.

DIZZINESS

Complaints of dizziness must be separated into three different categories: vertigo, disequilibrium, and dizziness. *Vertigo* is a hallucination of movement involving the patient or the environment. Vertigo often implies a spinning sensation but may also be experienced as a feeling of swaying back and forth or falling. All such characteristics are most often related to a peripheral vestibular lesion. Vertigo of peripheral origin is usually episodic, with normal periods between spells. It is accompanied by horizontal or rotatory-horizontal nystagmus with nausea and vomiting. *Disequilibrium* or *ataxia* is a feeling of unsteadiness on walking. Patients may feel normal when they are stationary, but they notice difficulty in walking. Often, they have no symptoms of vertigo or dizziness. Disequilibrium suggests a central lesion. Patients with severe bilateral peripheral vestibular dysfunction may also note unsteady gait and oscillopsia, the symptom of nystagmus in which objects seem to be jumping from side to side or up and down while the patient is walking. *Dizziness* without spinning or disequilibrium is difficult for patients to describe. They mention light-headedness, sensations of swimming and floating, or giddiness. These symptoms have no localizing value and may be due to circulatory, metabolic, endocrine, degenerative, or psychologic factors. Peripheral vestibular and central lesions must be ruled out.

The sense of equilibrium and position in space is an integrated function of multiple peripheral sensory inputs into the brain, including the visual, vestibular, and proprioceptive systems. The vestibular system plays a dual role, responding to gravity and linear acceleration through the utricle and saccule, and to angular acceleration through the semicircular canals. If insufficient or conflicting information is presented to the central nervous system, different degrees of dizziness result. Spinning vertigo, associated with nystagmus, nausea, and vomiting and aggravated by head and body movement, suggests a peripheral vestibular lesion, especially if it is episodic and recurrent. Other symptoms suggesting a peripheral origin of these symptoms are accompanying hearing loss or tinnitus.

COMMON CAUSES OF DIZZINESS AND HEARING LOSS

Benign Positional Paroxysmal Vertigo

This condition is characterized by recurrent momentary episodes of vertigo that are brought on by changing head position, mainly with extension of the neck, by rolling over in bed from side to side, by rising from bed, or by bending down. The vertigo starts after a latency of a few seconds after the stimulating position is assumed. Vertigo builds to a peak before it subsides, usually lasting less than 1 minute. It is associated with rotatory nystagmus, beating toward the floor if the patient is lying down with the head turned toward the offending ear. As the patient sits up or turns to a neutral position, a few beats of nystagmus are experienced, with the rapid phase toward the opposite side. These symptoms can be re-produced in the office by positional testing. The patient is asked to lie down quickly from a sitting position, with the head extended and turned all the way to one side. Benign paroxysmal vertigo is fatigable. Repeating the positional test abolishes the response.

Known causes of the syndrome include head trauma, labyrinthitis, and aging. Histologic sections of temporal bones from affected patients have shown otoconia in the posterior semicircular canal ampulla. These calcium carbonate crystals are normally found in the utricle and the saccule; they are thought to have been dislodged into the posterior canal and consequently to stimulate the vertigo, thus the term *cupulolithiasis*.

The natural history of benign positional vertigo is spontaneous resolution. Most patients are free of symptoms within a few weeks or months. Symptoms can be abolished by a variety of positioning exercises, the most successful and frequently performed being the Epley maneuver. Labyrinthine suppressants, such as meclizine hydrochloride (Antivert) and diazepam, may reduce the intensity of the vertigo. Avoiding the offending position is highly effective in avoiding the symptoms. If disabling positional vertigo persists for more than 1 year despite multiple maneuvers and conservative medical management, section of the posterior ampullary nerve (singular neurectomy) through a middle ear approach often abolishes the vertigo while preserving hearing. Another highly successful procedure is obliteration of the posterior semicircular canal through a transmastoid approach. Hearing and the remainder of the vestibular function are preserved through either procedure.

The syndrome must be differentiated from other positional vertigo conditions ([Table 6.1](#)). Otologic evaluation with audiologic and vestibular testing may be necessary for final diagnosis.

	Age	Latency	Duration	Frequency	Rotation	Location
Peripheral	20-50 years	1-2 sec	<1 min	1-2 times	Horizontal or vertical	Unilateral
Central	50-70 years	1-2 sec	>1 min	1-2 times	Horizontal or vertical	Bilateral

Reprinted from *Otolaryngology*, 1991, 115, 100-101.

TABLE 6.1. DIFFERENTIATION BETWEEN PERIPHERAL AND CENTRAL PAROXYSMAL POSITIONAL NYSTAGMUS

Vestibular Neuronitis

In this condition, vertigo occurs suddenly and severely with vomiting and nystagmus; it may last several days. There are no cochlear symptoms, and audiologic tests are normal. Caloric tests show a reduced response on the affected side. The patient may feel unsteady for several weeks after an attack. Recurring attacks usually seem less severe than the first and may continue for several months. The syndrome results from a sudden loss of function of one vestibular system; it is analogous to sudden loss of hearing. Vestibular neuronitis may follow an overt viral illness. In most cases, however, the cause is unknown. A brief course of vestibular suppressants followed by encouragement of physical activity may shorten the duration of disability by enhancing vestibular compensation.

Meniere Syndrome

This illness is characterized by recurrent attacks of tinnitus, hearing loss, and vertigo accompanied by a sense of pressure in the ear, distortion of sounds, and sensitivity to noise. All the symptoms may not occur at the same time in the same spell. Hearing loss or vertigo may even be absent for several years. Symptoms occur in clusters with variable periods of remission that may last for several years. Major attacks of vertigo with nausea and vomiting last from a few minutes to many hours and may force cessation of all usual activities. Minor spells are characterized by unsteadiness, giddiness, or light-headedness. Hearing loss begins as a low-frequency cochlear type of hearing loss that improves between attacks. In severe cases, hearing loss becomes slowly progressive and persistent, with a flat configuration on the audiogram. Symptoms are usually unilateral but become bilateral in 20% to 30% of patients with long-term follow-up. The pathogenesis is unknown.

A typical histopathologic feature of Meniere syndrome, *endolymphatic hydrops*, consists of an increase in the endolymphatic fluid pressure and volume with ballooning of the cochlear duct, utricle, and saccule. As in other conditions characterized by increased extracellular fluid volume, symptoms are aggravated by salt-loading and may be helped by reducing dietary intake of salt or by giving diuretics. In the few patients who are incapacitated by major spells of vertigo, ablative surgery is used through either a labyrinthectomy, when there is no useful hearing, or a vestibular nerve section that spares the cochlear nerve in patients with serviceable hearing. Endolymphatic sac decompression and shunt are another commonly performed procedure when hearing preservation is desired. However, the long-term success

rates in vertigo control are better with vestibular neurectomy.

Meniere syndrome must be separated from congenital or tertiary syphilis, which also causes endolymphatic hydrops, vertigo, and hearing loss. In syphilis, hearing loss is progressive and usually bilateral. Cogan syndrome also resembles Meniere syndrome with endolymphatic hydrops, hearing loss, and vertigo. In Cogan syndrome, in addition, ocular inflammation occurs without evidence of syphilis. Cogan syndrome is thought to be an autoimmune condition, which may also be true of Meniere syndrome.

Perilymphatic Fistula

Hearing loss with or without vertigo may follow sudden changes of pressure in the middle ear or cerebrospinal fluid that may be due to weight lifting, barotrauma from scuba diving or flying, or even forceful coughing or nose blowing. Perilymphatic fistula may arise spontaneously, especially in children with congenital defects of the inner ear. Stapedectomy also increases the risk for perilymphatic fistula. Surgery to patch the fistula may be necessary in selected patients to stop progression of the symptoms.

Cerebellopontine Angle Tumors

The most common tumor involving the cerebellopontine angle is the acoustic neuroma (schwannoma). By the time loss of corneal reflex, cerebellar signs, gross nystagmus, and facial weakness are seen, the tumor is large. Because the earliest symptoms are tinnitus, hearing loss, and dizziness, this tumor must always be considered in the evaluation of a patient with any of these symptoms. Early diagnosis is particularly important because improvement in microsurgical techniques has made possible complete removal of the tumor without damaging the facial nerve, and even preservation of useful hearing if the tumor is small. "Dizziness" is rarely true vertigo and does not occur in recurrent attacks; rather, there is a persistent sense of unsteadiness or light-headedness. All patients with tinnitus, hearing loss, or dizziness must have audiometric testing, including impedance testing with stapedial reflex evaluation. If the initial evaluation suggests a neural site of hearing loss, then electronystagmography with a caloric test and a brainstem auditory evoked response test should be carried out. Magnetic resonance imaging with gadolinium enhancement is the definitive test in the diagnosis of acoustic neuroma.

Drug Toxicity

Salicylates, aminoglycoside antibiotics, furosemide (Lasix), anticonvulsants, and alcohol can cause dizziness in the form of vertigo, disequilibrium, and light-headedness. Tinnitus and hearing loss may also occur. These symptoms are bilateral and are often accompanied by ataxic gait, as they variously affect the vestibular and cochlear apparatuses. Sedatives (e.g., diazepam, phenobarbital), antihistamines, mood elevators, and antidepressants can also cause light-headedness and disequilibrium. Recent intake of possibly toxic drugs should be reviewed with any patient complaining of "dizziness." Cessation of use of a drug usually causes clearing of the symptoms in a few days, although vestibular and cochlear damage due to aminoglycosides and other ototoxic drugs can result in permanent ataxia or hearing loss.

Craniocerebral Injuries

Loss of hearing, tinnitus, and vertigo (often postural) can be sequelae of head injury. Hearing loss may be due to a fracture in the middle ear ossicles or the cochlea. Vertigo may be due to concussion or hemorrhage into the labyrinth or a perilymphatic fistula. Postural vertigo may be a nonspecific reaction to concussion and part of the postconcussion syndrome, or may be secondary to posttraumatic cupulolithiasis and benign paroxysmal vertigo.

Cardiac Arrhythmia

Cardiac arrhythmias sufficient to lower cardiac output can cause dizziness. The patient may not notice palpitations. If a cardiac arrhythmia is suspected, 24- to 48-hour continuous electrocardiograph monitoring (Holter monitor) may help establish the relationship of arrhythmias to episodes of dizziness.

End-organ Degeneration

With the increase in life expectancy, many patients now reach ages at which degenerative losses cause disequilibrium. Past a certain age (which is different for each patient), there is an almost linear decline in the numbers of hair cells in the cochlea and of nerve fibers in the vestibular nerve; deterioration of other sensory systems (i.e., visual, proprioceptive, exteroceptive, and auditory) and of the ability to integrate information from those sensory systems causes disequilibrium in older patients. Older patients also lose cerebral adaptive functions and cannot compensate for the loss of sensory function.

Psychophysiologic Causes of Vertigo: Hyperventilation

Acute anxiety attacks or panic attacks can cause vertigo. It is not always easy to differentiate psychophysiologic cause and effect because vertigo can sometimes trigger acute anxiety or panic attacks. The history usually includes a period of external stress, fear of blacking out, fear of dying, shortness of breath, palpitations, tingling or weakness in the hands, mouth, or legs, and frequent or daily occurrence. Whirling vertigo is uncommon. These spells are often induced by hyperventilation. Asking the patient to hyperventilate for 2 minutes will evoke the typical symptoms. Patients with anxiety, depression, and panic attacks may respond to specific therapy and the appropriate psychopharmacologic agents.

Other Causes of Dizziness

Dizziness may be a secondary effect of a variety of disorders, including the following:

- Migraine (vertebrobasilar type)
- Multiple sclerosis
- Neurosyphilis
- Cervical spondylosis
- Sensory deprivation (e.g., polyneuropathy, visual impairment)
- Vertebrobasilar insufficiency (e.g., transient ischemic attack, infarction)
- Cerebellar hemorrhage
- Anemia
- Orthostatic hypotension
- Intralabyrinthine hemorrhage (e.g., leukemia, trauma)
- Carotid sinus syncope
- Diabetes mellitus
- Hypoglycemia

TAKING THE HISTORY

The first step in taking the patient's history is to determine whether the patient is suffering from vertigo, disequilibrium, light-headedness, motor incoordination, seizure, syncope, or a combination of these. It is necessary to determine the time of onset, temporal pattern, associated symptoms, and factors that seem to precipitate, aggravate, or relieve symptoms. If there are episodes, the sequence of events needs to be known, including activities at onset, possible aura, quality, severity, sequence of symptoms, and the patient's response during the attack. Does the patient have to sit or lie down? Is consciousness lost? Can someone communicate with the patient during an attack? What other symptoms occur? After an attack, how does the patient feel? Can the patient remember the events that occurred during an attack? Can the patient function normally following an attack? These considerations suggest specific questions that must be asked in taking the history. The following list contains examples of the kinds of specific questions that should be put to the patient:

1. Is the dizziness precipitated by head movement? (Benign positional vertigo is characteristically precipitated by head movement, but orthostatic hypotension causes dizziness on rising from sitting or lying. Neck movements may precipitate dizziness in cervical osteoarthritis or muscle spasm. Head turning may precipitate dizziness with carotid sinus syncope if the patient is wearing a tight collar.)

2. If there is vertigo, is it rotational? Does the patient have a veering gait or an unsteady stance with nausea, perspiration, and tachycardia? In which direction does the vertigo occur?
3. Are cochlear and vestibular symptoms associated? (This pattern would suggest a peripheral lesion affecting both portions of the inner ear or eighth cranial nerve.)
4. Has there been recent head trauma?
5. Are there other neurologic symptoms, such as visual changes, paralysis, sensory alterations, altered consciousness, or headaches? (These symptoms might suggest a more generalized neurologic disorder in which dizziness and hearing loss are only a part.)
6. Is there numbness in the hands and feet, visual impairment, or a history of diabetes or anemia? (Sensory loss in the elderly or chronically debilitated patient can lead to environmental disorientation that is interpreted as dizziness.)
7. Are there cardiac symptoms (e.g., tachycardia, palpitation, or angina) that suggest a cardiac disorder?
8. Are there psychiatric symptoms (e.g., thought disorders, delusions, hallucinations, bizarre behavior, or depression) that suggest dizziness of a psychic nature? Do symptoms of anxiety suggest possible hyperventilation?
9. Transient ischemic attacks may cause recurrent dizziness. Inquiry should include questions about other recurrent symptoms of vertebrobasilar ischemia, as well as risk factors (e.g., hypertension and cardiovascular disease).
10. Is there a familial history of dizziness or hearing loss?

CONCLUSION

Diagnosing dizziness, disequilibrium, or vertigo can be a challenging task. The differential diagnosis is spread across medical specialties and may require multiple consultations. If symptoms are persistent, neurologic and neurotologic evaluations are indicated. An accurate clinical history, appropriate examinations, and tests of audiologic and vestibular systems are needed for accurate diagnosis and effective treatment.

CHAPTER 7. IMPAIRED VISION

MYLES M. BEHRENS

[Ocular Lesions](#)
[Optic Nerve Lesions](#)
[Lesions of the Optic Chiasm](#)
[Retrochiasmal Lesions](#)
[Impairment of Ocular Motility](#)
[Suggested Readings](#)

Impaired vision may be due to a lesion within the eyes, in the retrobulbar visual pathway (including the optic nerve and optic chiasm), or in the retrochiasmal pathway. The retrochiasmal pathway includes the optic tract, geniculate body (where synapse occurs), the visual radiation through the parietal and temporal lobes, and the occipital cortex. The pattern of visual loss may identify the site of the lesion. The course and accompanying symptoms and signs may clarify its nature.

OCULAR LESIONS

Impaired vision of ocular origin may be caused by refractive error, opacity of the ocular media (which may be seen by external inspection or ophthalmoscopy), or a retinal abnormality (e.g., retinal detachment, inflammation, hemorrhage, vascular occlusion). There may be associated local symptoms or signs, such as pain or soft tissue swelling.

OPTIC NERVE LESIONS

A visual defect may originate in the optic nerve, particularly if the symptoms affect only one eye. The hallmarks of optic nerve dysfunction include blurred vision (indicated by decreased visual acuity), dimming or darkening of vision (usually with decreased color perception), and decreased pupillary reaction to light. This pupillary sign is not seen if the problem is media opacity, minor retinal edema, or nonorganic visual loss. It may be present to a mild degree in simple amblyopia.

The *relative afferent pupillary defect* results from an optic nerve lesion in one eye; the sign is best shown by the swinging-flashlight test. A bright flashlight is swung from one eye to the other just below the visual axis while the subject stares at a distant object in a dark room. Constriction of the pupils should be the same when either eye is illuminated. However, if an eye with optic nerve dysfunction is illuminated, the pupils constrict less quickly in response to the light, less completely, and less persistently than when the normal fellow eye is illuminated. If the expected constriction does not occur or if the pupils actually dilate after an initial constriction on stimulation of one eye, the test is positive. Both pupils are equal in size at all times in purely afferent defects because there is hemidecussation of all afferent light input to the midbrain with equal efferent stimulation through both third cranial nerves. Therefore, if one pupil is fixed to light because of an efferent defect, the other one can be observed throughout the performance of this test.

The patient may be aware of, or the examiner may find, a *scotoma* (blind spot) in the visual field. This is often central or centrocecal (because the lesion affects the papillomacular bundle that contains the central fibers of the optic nerves), or altitudinal (because arcuate or nerve-fiber-bundle abnormalities respect the nasal horizontal line, corresponding to the separation of upper and lower nerve-fiber bundles by the horizontal raphe in the temporal portion of the retina). These abnormalities are often evident on confrontation tests of the visual fields.

In a central scotoma of retinal origin (e.g., due to macular edema affecting photoreceptors), the patient may report that lines seem to be distorted (*metamorphopsia*) or objects may seem small (*micropsia*). Recovery of visual acuity may be delayed (e.g., in comparison to a normal fellow eye) after photostress, such as a flashlight stimulus for 10 seconds.

Bilateral optic nerve abnormalities, in particular those with centrocecal scotomas ([Fig. 7.1A](#)), suggest a hereditary, toxic, nutritional, or demyelinating disorder; unilateral optic nerve disease is usually ischemic, inflammatory, or compressive. The course and associated symptoms and signs help differentiate these possibilities.

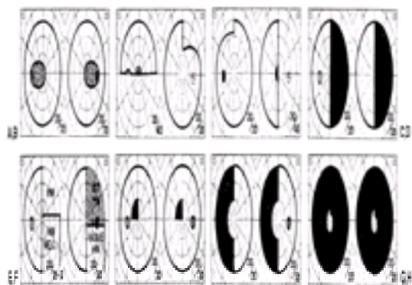

FIG. 7.1. **A:** Bilateral centrocecal scotoma. **B:** Inferior altitudinal defect with central scotoma O.S. (left eye) and upper temporal hemianopic (junctional) defect O.D. (right eye). **C:** Bitemporal hemianopia. **D:** Total right homonymous hemianopia. **E:** Incongruous right homonymous hemianopia. **F:** Congruous left homonymous hemianopic scotoma. **G:** Left homonymous hemianopia with macular sparing. **H:** Bilateral congruous homonymous hemianopia.

Optic nerve infarction (anterior ischemic optic neuropathy) usually affects patients older than 50 years. The visual defect is usually primarily altitudinal, occasionally centrocecal, sudden in onset, and stable (occasionally progressive during the initial weeks). There is pallid swelling of the optic disc with adjacent superficial hemorrhages. The swelling resolves in 4 to 6 weeks, leaving optic atrophy and arteriolar narrowing on the disc ([Fig. 7.2](#)). The cause may be arteritis (giant cell or temporal arteritis, often with associated symptoms and signs) but is usually idiopathic, painless, and only rarely associated with carotid occlusive disease. In the idiopathic nonarteritic variety, the discs are characteristically crowded, with small, if any, physiologic cup, thus suggesting structural susceptibility. The fellow eye is often similarly affected after months or years.

FIG. 7.2. **A:** Pallid swelling of the disc with superficial hemorrhages in a patient with acute anterior ischemic optic neuropathy. **B:** Optic atrophy with arteriolar narrowing after anterior ischemic optic neuropathy.

Optic neuritis usually affects young adults. It typically begins with a central or centrocecal scotoma and subacute progression of the defect that is followed by a gradual resolution; there may be residual optic atrophy. Initially, the disc may be normal (retrobulbar neuritis) or swollen (papillitis). Local tenderness or pain on movement of the eye is usually present and suggests such an intraorbital inflammatory disorder. The *Pulfrich phenomenon* is a stereo illusion that may be caused by delayed conduction in one optic nerve, making it difficult to localize moving objects. This is not specific and may occur with retinal abnormality or media defect. The *Uhthoff symptom* is an exacerbation of a symptom after exercise or exposure to heat; it is not specific but occurs most often in demyelinating disorders. If in a case suggesting optic neuritis there is evidence of preexisting optic atrophy in either eye or optic neuropathy in the fellow eye (e.g., if the degree of relative afferent pupillary defect is less than anticipated, suggesting subclinical involvement of the other eye), demyelinating disease is also suggested.

In *compressive optic neuropathy*, there is usually steady progression of visual defect, although it may be stepwise or even remitting. The disc may remain relatively normal in appearance for months before primary optic atrophy is indicated funduscopically by decrease in color of the disc, visible fine vessels on the disc, and peripapillary nerve fibers (best seen with a bright ophthalmoscope with red-free light). This form of optic atrophy must be distinguished from other specific types (e.g., glaucoma, in which the nerve head has an excavated or cupped appearance; postpapilledema [secondary] atrophy with narrowing and sheathing of vessels and often indistinct margins; retinal pigmentary degeneration with narrowed vessels, which may also be seen after central retinal artery occlusion or optic nerve infarction; and congenital defects, such as coloboma or hypoplasia of the disc, with a small nerve head and a peripapillary halo that corresponds to the expected normal size of the disc).

LESIONS OF THE OPTIC CHIASM

In a patient with optic neuropathy, recognition of an upper temporal hemianopic visual-field defect (which may be asymptomatic) in the other eye is evidence of a chiasmal lesion that affects the anteriorly crossing lower fibers (see [Fig. 7.1B](#)). In contrast to optic nerve lesions, the majority of chiasmal lesions are compressive. The typical visual-field defect is bitemporal hemianopia (see [Fig. 7.1C](#)). Because the macular fibers permeate the chiasm, any compressive lesion of the chiasm with a visual-field defect is accompanied by temporal hemianopic dimming of red objects of any size in a pattern that respects the vertical line and permits secure confrontation testing.

RETROCHIASMAL LESIONS

Homonymous hemianopia results from a retrochiasmal lesion. There may be varying awareness of the defect. It may be mistakenly attributed to the eye on the side of the defect, or the patient may be aware only of bumping into things on that side or of trouble reading (slowness and difficulty seeing the next word with right homonymous hemianopia, or difficulty finding the next line with left hemianopia). The patient may ignore that side of the visual acuity test chart that corresponds to the hemianopia, but can see 20/20 unless there is another defect (see [Fig. 7.1D](#)).

With subtotal lesions, the congruity of the visual-field defect in the two eyes helps in localization. Optic tract and geniculate lesions tend to have grossly incongruous visual-field defects (see [Fig. 7.1E](#)). The farther posterior that the lesion is, the more congruous is the defect because the fibers from corresponding retinal loci in the two eyes converge on the same occipital locus.

With optic tract lesions anterior to the geniculate synapse, *optic atrophy* may develop. The eye with a temporal field defect develops a bow-tie pattern of atrophy, which may also occur with chiasmal lesions. The nasal portion of the disc is pale due to loss of the nasal fibers; the usual mild temporal pallor is more evident due to loss of the nasal half of the papillomacular bundle. An imaginary vertical line through the macula corresponds to the vertical line that separates the nasal and temporal halves of the visual field. There is a relatively pink appearance above and below where fibers from the temporal retina reach the disc.

With optic tract lesions, afferent pupillary input is impaired. When the lesion is grossly incongruous, a relative afferent pupillary defect may occur on the side with the greater deficit. It is found in the eye with temporal hemianopia when homonymous hemianopia is total, because the temporal half-field is more extensive than the nasal half-field. The *Wernicke hemianopic pupillary phenomenon* may be difficult to elicit: Pupillary constriction is more vigorous when the unaffected portion of the retina is stimulated. When an optic tract lesion is close to and encroaches on the chiasm, visual acuity in the ipsilateral eye diminishes. There may be a relative afferent pupillary defect on that side, as well.

Retrogeniculate lesions are not accompanied by clinical impairment of pupillary reactivity or optic atrophy. The homonymous hemianopic visual-field defect tends to be superior when the temporal lobe radiations are affected, and the defect is denser below if the lesion is parietal. Occipital lesions result in precisely congruous defects, often scotomas with preserved peripheral vision (see [Fig. 7.1F](#)). If the scotoma is large enough, the area of preserved peripheral vision may be present only in the eye with the loss of temporal field (a preserved temporal crescent). This corresponds to the most anterior portion of the occipital cortex. The central portion of the visual field is represented in the posterior striate cortex, a marginal perfusion zone of both posterior and middle cerebral arteries. When the posterior cerebral artery is occluded, collateral supply from the middle cerebral artery may allow gross *macular sparing* (see [Fig. 7.1G](#)), preserving central vision. Homonymous hemianopia of occipital origin is often total. Isolated homonymous hemianopia is due to an infarct in 90% of patients. *Cerebral blindness* (bilateral homonymous hemianopia [see [Fig. 7.1H](#)]) may require distinction from hysterical blindness; optokinetic nystagmus (OKN) can be elicited in psychogenic disorders, but not after bilateral occipital lesions when they are complete.

Irritative visual phenomena include formed visual hallucinations (usually of temporal lobe origin) and unformed hallucinations (usually of occipital origin), including the *scintillating homonymous scotoma* of migraine. *Amaurosis fugax* of one eye is occasionally due to vasospasm in migraine but is usually due to ophthalmic-carotid hypoperfusion or embolization, or cardiogenic emboli. Formed or unformed hallucinations may be release phenomena when there is visual loss due to a lesion anywhere along the visual pathway. *Phosphenes* (light flashes) may occur in several kinds of optic nerve lesions, including demyelinating optic neuritis, or they may occur with movement of the eye. Vitreoretinal traction is a frequent and nonsinister cause of light flashes, especially with advancing age, although a retinal tear premonitory to retinal detachment may occur and must be ruled out.

IMPAIRMENT OF OCULAR MOTILITY

Impairment of ocular motility is often a clue to diagnosis in many neurologic disorders. It may reflect a supra-, inter-, or infranuclear (fascicular or peripheral nerve) neurogenic lesion, neuromuscular transmission defect, myopathy, or mechanical restriction in the orbit. *Diplopia* (double vision) indicates malalignment of the visual axes if it is relieved by occlusion of either eye. Diplopia of monocular origin is psychogenic or due to a disturbance of the refractive media in the eye (e.g., astigmatism or opacity of the cornea or lens). Malalignment of the visual axes may occur in psychogenic convergence spasm (suggested by associated miosis due to the near response), in decompensation of strabismus (including convergence insufficiency, usually of no pathologic import), and, less frequently, in divergence insufficiency (possibly due to bilateral sixth cranial nerve paresis, occasionally caused by increased intracranial pressure). The diplopia and malalignment of the visual axes in these cases are usually committant, that is, equal in all directions of gaze. If strabismus begins in early childhood, there may be habitual suppression of the image of one eye, with impaired development of vision in that eye (*amblyopia*) rather than diplopia.

Incommittance, or inequality in the alignment of the visual axes in the direction of gaze, suggests limitation of action of one or more muscles. The deviation is generally greater if the paretic eye is fixing. The patient may use one eye or adopt a head-turn or tilt to avoid diplopia (e.g., turning to the right when the right lateral rectus is limited, or tilting to the left if the right superior oblique is affected, to avoid the need for the intortional effect of that muscle). The patient may not be aware of either the diplopia or these adaptations.

To determine which muscle is impaired, the examiner obtains information from the history and examination (including use of a red glass). It is important to know whether the diplopia is vertical or horizontal, whether it is crossed (if the visual axes are divergent) or uncrossed (if convergent), whether greater near (if adducting muscles are involved) or at a distance (if abducting muscles are involved), and the direction of gaze in which the diplopia is maximal.

If the pattern of motility limitation conforms to muscles innervated by a single nerve, the lesion probably affects that nerve. With a third cranial nerve palsy, there is ptosis, limitation of action of the medial, inferior, and superior rectus muscles and of the inferior oblique muscle; that is, all the extraocular muscles are affected except the lateral rectus (sixth cranial nerve) and superior oblique (fourth cranial nerve). *Internal ophthalmoplegia* (i.e., pupillary enlargement with defective constriction and defective accommodation) may be evident. When the ptotic lid is lifted, the eye is abducted (unless the sixth cranial nerve is also affected), and on attempted downward gaze the globe can be seen to intort (by the observation of nasal episcleral vessels) if the fourth cranial nerve is intact. If more than one of these nerves is affected, the lesion is probably in the cavernous sinus, superior orbital fissure, or orbital apex. There may also be fifth cranial nerve (ophthalmic division) and

oculosympathetic defect (*Horner syndrome*). The latter is indicated by relative miosis, mild ptosis, and incomplete and delayed dilation of the pupil. Such involvement is usually due to tumor, aneurysm, or inflammation, whereas isolated involvement of one of the ocular motor nerves may be ischemic.

Mechanical limitation of ocular motility may occur with orbital lesions, such as thyroid ophthalmopathy, orbital fracture, or tumor. It is indicated by limitation on forced duction, such as an attempt to rotate the globe with forceps (traction test), or by elevation of intraocular pressure on the attempted movement with relatively intact velocity saccades (i.e., rapid eye movements). Other symptoms or signs of orbital lesions include proptosis (or enophthalmos in the case of fracture) beyond acceptable normal asymmetry of 2 mm, resistance to retropulsion, vascular congestion, tenderness, and eyelid abnormality other than ptosis (e.g., retraction, lid-lag, swelling).

Myasthenia gravis (see [Chapter 120](#)) is suggested when affected muscles do not conform to the distribution of a single nerve (although they may) and when symptoms vary, including diurnal fluctuation and fatigability. A demonstrable increase in paresis or a slowing of saccades may occur after sustained gaze or repetitive movement. Ptosis may similarly increase after sustained upward gaze (or lessen after rest in sustained eye closure) or a momentary lid twitch may be seen on return of gaze from downward to straight ahead. There is no clinical abnormality of the pupils in myasthenia gravis.

Analysis of saccadic function is of particular value in the analysis of supra- and internuclear ocular motility defects. The supranuclear control mechanisms of ocular movements include the *saccadic system* of rapid conjugate eye movement of contralateral frontal lobe origin to achieve foveal fixation on a target (a combination of *pulse*, burst discharge in agonist with total inhibition of antagonist, and *step*, increased level of agonist and decreased level of antagonist discharge to maintain the new eccentric position); the *pursuit system* of slow conjugate movement of ipsilateral occipital lobe origin to maintain foveal fixation on a slowly moving target; the *vestibular system* of slow conjugate movement to maintain stability of the retinal image if the head moves in relation to the environment; and the *vergence system* of dysconjugate slow movement to maintain alignment of the visual axes for binocular single vision. OKN is the normal response to a sequence of objects moving slowly across the field of vision and can be considered a combination of pursuit and refixation saccades (to allow continuous pursuit, because vision is suppressed during the saccadic phase).

The polysynaptic saccadic pathway crosses at the level of the fourth cranial nerve nucleus to enter the *pontine paramedian reticular formation* (PPRF), where ipsilateral saccades and other horizontal movements are generated by stimulation of neurons in the sixth cranial nerve nucleus and also interneurons therein that travel up the opposite *medial longitudinal fasciculus* (MLF) to stimulate the contralateral subnucleus for the medial rectus in the third cranial nerve nucleus to assure normal conjugate gaze. Pathways for vertical movement seem to require bilateral stimuli. The immediate supranuclear apparatus for generating vertical gaze is in the midbrain, the rostral interstitial nucleus of the MLF.

General dysfunction of saccades (with limitation, slowing, or hypometria) is seen in several disorders, including Huntington disease (see [Chapter 108](#)), hereditary cerebellar degeneration (see [Chapter 107](#)), progressive supranuclear palsy (see [Chapter 115](#)), and Wilson disease (see [Chapter 89](#)). *Congenital ocular motor apraxia* is a benign abnormality of horizontal saccades that resolves with maturity. Infants with this abnormality are unable to perform horizontal saccades and substitute characteristic head thrusts past the object of regard, achieving fixation by the contraversive vestibular doll's-head movement and then maintaining it while slowly rotating the head back. Focal dysfunction of saccades is manifested by lateral gaze paresis after contralateral frontal or ipsilateral pontine lesions; vestibular stimuli may overcome frontal gaze palsies but do not affect pontine lesions.

Internuclear ophthalmoplegia is the result of a lesion in the MLF that interrupts adduction in conjugate gaze (but convergence may be intact). Abduction nystagmus is seen in the contralateral eye. When the defect is partial, adducting saccades are slow, with resultant dissociation of nystagmus again more marked in the abducting eye, as when OKN is elicited. When the lesion is unilateral, an ischemic lesion is likely; a bilateral syndrome suggests multiple sclerosis. Vertical gaze-evoked nystagmus and *skew deviation* (one eye higher than the other) may be seen. The latter is a supranuclear vertical divergence of the eyes, seen with brainstem or cerebellar lesions.

A unilateral pontine lesion that involves both the MLF and PPRF causes the combination of ipsilateral gaze palsy and internuclear ophthalmoplegia on contralateral gaze, a pattern called the *1 1/2 syndrome*. The only remaining horizontal movement is abduction of the contralateral eye. The eyes are straight or exodeviated (if there is gaze preference away from the side of the gaze palsy). Superimposed esodeviation with related diplopia may occur if there is sixth cranial nerve (fascicular) involvement, as well.

Vertical gaze disorders are seen with midbrain lesions (the *sylvian aqueduct syndrome*). Characteristic dyssynergia on attempted upward saccades is best demonstrated by downward moving OKN stimuli: Failure of inhibition leads to co-firing of oculomotor neurons with convergence-retraction nystagmus and related fleetingly blurred vision or diplopia. This may also occur, to a lesser extent, with horizontal saccades, causing excessive adductor discharge and "pseudo sixth cranial nerve paresis." There is usually pupillary sluggishness in response to light (often with light-near dissociation) due to interruption of the periaqueductal afferent light input to the third cranial nerve nuclei. Concomitant abnormalities may include lid retraction (*Collier sign*), defective or excess accommodation or convergence, and skew deviation or monocular elevator palsy.

Oscillopsia is a sensation of illusory movement of the environment that is unidirectional or oscillatory; it is seen with acquired nystagmus of various types. *Nystagmus* is an involuntary rhythmic oscillation of the eyes, generally conjugate and of equal amplitude but occasionally dysconjugate (as in the sylvian aqueduct syndrome) or dissociated in amplitude (as in internuclear ophthalmoplegia). The oscillations may be pendular or jerk in type; the latter is more common in acquired pathologic nystagmus. In jerk nystagmus, the slow phase is operative and the fast phase is a recovery movement. The amplitude usually increases on gaze in the direction of the fast phase.

Horizontal and upward gaze-evoked nystagmus may be due to sedative or anticonvulsant drugs. Otherwise, *vertical nystagmus* indicates posterior fossa disease. Extreme end-gaze physiologic nystagmus, which may be of greater amplitude in the abducting eye, must be distinguished. It occurs only horizontally. *Jerk nystagmus* in the primary position, or rotatory nystagmus, usually indicates a vestibular disorder that may be either central or peripheral. In a destructive peripheral lesion, the fast phase is away from the lesion; the same pattern is seen with a cold stimulus when the horizontal canals are oriented vertically (i.e., with the head elevated 30 degrees in the supine position). *Downbeating nystagmus* in the primary position, often more marked on lateral gaze to either side, frequently indicates a lesion at the cervicomedullary junction. *Ocular bobbing* is usually associated with total horizontal pontine gaze palsy; it is not rhythmic, is coarser than nystagmus, may vary in amplitude, and is occasionally asymmetric; the initial movement is downward with a slower return. *Upbeating nystagmus* in the primary position may indicate a lesion of the cerebellar vermis or medulla but most commonly the pons. *Seesaw nystagmus* is vertically dysconjugate with a rotatory element, so that there is intortion of the elevating eye and simultaneous extortion of the falling eye. This pattern is often seen with parachiasmatic lesions and is probably a form of alternating skew deviation due to involvement of vertical and torsional oculomotor control regions around the third ventricle. *Periodic alternating nystagmus* implies a nonsinister lesion of the lower brainstem; in effect, it is a gaze-evoked nystagmus to either side of a null point that cycles back and forth horizontally. In the primary position, there is nystagmus of periodically alternating direction. *Rebound nystagmus*, which may be confused with periodic alternating nystagmus, is a horizontal jerk nystagmus that is transiently present in the primary position after sustained gaze to the opposite side; it implies dysfunction of the cerebellar system.

Other ocular oscillations that follow cerebellar system lesions include *ocular dysmetria* (overshoot or terminal oscillation of saccades), *ocular flutter* (bursts of similar horizontal oscillation, actually back-to-back saccades without usual latency), *opsoclonus* (chaotic multidirectional conjugate saccades), and *fixation instability* (square-wave jerks), in which small saccades interrupt fixation, with movement of the eye away from the primary position and then its return after appropriate latency for a saccade. *Ocular myoclonus* is a rhythmic ocular oscillation that often is vertical and associated with synchronous palatal myoclonus.

When oscillopsia is monocular, there may be dissociated pathologic nystagmus of posterior fossa origin, including the jellylike, primarily vertical, pendular nystagmus akin to myoclonus that is occasionally seen in multiple sclerosis. There may be benign myokymia of the superior oblique muscle, in which the patient is often aware of both a sensation of ocular movement and oscillopsia. Monocular nystagmus may also result from monocular visual loss in early childhood or from the insignificant and transient acquired entity of *spasmus nutans*, which is of uncertain etiology. It begins after 4 months of age and disappears within a few years. The nystagmus of spasmus nutans is asymmetric and rapid and may be accompanied by head nodding. It may be similar to congenital nystagmus. The latter begins at birth, persists, and is usually horizontal, either gaze-evoked or pendular, often with jerks to the sides, and there may be a null with head turn adopted for maximal visual acuity. It originates in a motor disorder, although it may be mimicked by the nystagmus of early binocular visual deprivation.

CHAPTER 8. HEADACHE

NEIL H. RASKIN

[General Principles](#)
[Pain-Sensitive Structures of the Head](#)
[Approach to the Patient with Headache](#)
[Suggested Readings](#)

Nearly everyone is subject to headache from time to time; moreover, 40% of persons experience severe headaches annually. The mechanism generating headaches may be activated by worry and anxiety, but emotional stress is not necessary for the symptom to appear. Genetic factors may augment this system, so that some people are susceptible to more frequent or more severe head pain. The term *migraine* is increasingly being used to refer to a mechanism of this kind, in contradistinction to prior usage of the term as an aggregation of certain symptoms. Thus, stress-related or *tension* headaches, perhaps the most common syndrome reported by patients, is an example of the expression of this mechanism when it is provoked by an adequate stimulus; it may also be activated in some people by the drinking of red wine, by exposure to glare or pungent odors, or premenstrually.

Headache is usually a benign symptom and only occasionally is a manifestation of a serious illness, such as brain tumor or giant cell arteritis. The first issue to resolve in the care of a patient with headache is to make the distinction between benign and more ominous causes. If the data supporting a benign process are strong enough, as reviewed in this chapter, neuroimaging can be deferred. If a benign diagnosis cannot be made, magnetic resonance imaging is a better choice than computed tomography (CT) for visualizing the posterior fossa; posterior fossa tumors are far more likely than forebrain tumors to cause headache as the only symptom. Moreover, the Arnold-Chiari malformation, an important structural cause of headache, cannot be visualized with CT.

GENERAL PRINCIPLES

The quality, location, duration, and time course of the headache and the conditions that produce, exacerbate, or relieve it should be elicited.

Most headaches are dull, deeply located, and aching in quality. Superimposed on such nondescript pain may be other elements that have greater diagnostic value; for example, jabbing, brief, sharp pain, often occurring multifocally (*ice-picklike* pain), is the signature of a benign disorder. A throbbing quality and tight muscles about the head, neck, and shoulder girdle are common nonspecific accompaniments of headache that suggest that intra- and extracranial arteries and skeletal muscles of the head and neck are activated by a generic mechanism that generates head pain. Tight, pressing "hat-band" headaches were once believed to indicate anxiety or depression, but studies have not supported this view.

Pain *intensity* seldom has diagnostic value, nor does response to placebo medication provide any useful information. Administration of placebo simply identifies placebo responders, a group that includes about 30% of the population. No evidence reveals that placebo responders have lower pain levels than nonresponders or that they do not really have pain. Patients entering emergency departments with the most severe headache of their lives usually have migraine. Meningitis, subarachnoid hemorrhage, and cluster headache also produce intense cranial pain. Contrary to common belief, the headache produced by a brain tumor is not usually severe.

Data regarding headache *location* is occasionally informative. If the source is an extracranial structure, as in giant cell arteritis, correspondence with the site of pain is fairly precise. Inflammation of an extracranial artery causes scalp pain and extensive tenderness localized to the site of the vessel. Posterior fossa lesions cause pain that is usually occipitocervical, and supratentorial lesions most often induce frontotemporal pain. *Multifocality* alone is a strong indicator of benignity.

Time-intensity considerations are particularly useful. A ruptured aneurysm results in head pain that peaks in an instant, *thunderclap*-like manner; much less often, unruptured aneurysms may similarly signal their presence. *Cluster headache* attacks peak over 3 to 5 minutes, remain at maximal intensity for about 45 minutes, and then taper off. Migraine attacks build up over hours, are maintained for several hours to days, and are characteristically relieved by sleep. Sleep disruption is characteristic of headaches produced by brain tumors.

The relationship of a headache to certain biologic events or to physical environmental changes is essential information for triage of patients. The following exacerbating phenomena have high probability value in asserting that a headache syndrome is benign: provocation by red wine, sustained exertion, pungent odors, hunger, lack of sleep, weather change, or menses. The association of diarrhea with attacks is pathognomonic of a benign disorder (migraine). Cessation or amelioration of headache during pregnancy, especially in the second and third trimesters, is similarly pathognomonic. Patients with continuous benign headache often observe a pain-free interlude of several minutes on waking before the head pain begins once again. This phenomenon, wherein the cessation of sleep seems to unleash the headache mechanism, also occurs with other centrally mediated pain syndromes, such as thalamic pain, but does not occur among patients with somatic disease as the cause of pain.

A history of amenorrhea or galactorrhea leads to the possibility that the polycystic ovary syndrome or a prolactin-secreting pituitary adenoma is the source of headache ([Table 8.1](#)). Headache arising *de novo* in a patient with a known malignancy suggests either cerebral metastasis or carcinomatous meningitis. When the accentuation of pain is striking with eye movement, a systemic infection, particularly meningitis, should be considered. Head pain appearing abruptly after bending, lifting, or coughing can be a clue to a posterior fossa mass or the Arnold-Chiari malformation. Orthostatic headache arises after lumbar puncture and also occurs with subdural hematoma and benign intracranial hypertension. The eye itself is seldom the cause of acute orbital pain if the sclerae are white and noninjected; red eyes are a sign of ophthalmic disease. Similarly, acute sinusitis nearly always declares itself through a dark green, purulent nasal exudate.

Erythrocyte sedimentation rate
Antinuclear antibody titer
Thyroid microsomal antibody titer
Cardiolipin antibody titer
Serum prolactin level
Lumbar puncture (pressure, malignant cells)
Neuroimaging
Muscle biopsy (mitochondrial disorders, arteritis)
Temporal artery biopsy

TABLE 8.1. STUDIES PERFORMED TO INVESTIGATE CHRONIC HEADACHE

The analysis of facial pain requires a different approach. Trigeminal and glossopharyngeal neuralgias are common causes of facial pain, especially the trigeminal syndrome. *Neuralgias* are painful disorders characterized by paroxysmal, fleeting, often electric shocklike episodes; these conditions are caused by demyelinating lesions of nerves (the trigeminal or glossopharyngeal nerves in cranial neuralgia) that activate a pain-generating mechanism in the brainstem. *Trigger* maneuvers characteristically provoke paroxysms of pain. However, the most common cause of facial pain by far is dental; provocation by hot, cold, or sweet foods is typical. Application of a cold stimulus repeatedly induces dental pain, whereas in neuralgic disorders a refractory period usually occurs after the initial response so that pain cannot be induced repeatedly. The presence of refractory periods nearly always can be elicited in the history, thereby saving the patient from a painful experience.

Mealtimes offer the physician an opportunity to gain needed insight into the mechanism of a patient's facial pain. Does chewing, swallowing, or the taste of a food elicit pain? Chewing points to trigeminal neuralgia, temporomandibular joint dysfunction, or giant cell arteritis (*jaw claudication*), whereas the combination of

swallowing *and* taste provocation points to glossopharyngeal neuralgia. Pain on swallowing is common among patients with *carotidynia* (facial migraine), because the inflamed, tender carotid artery abuts the esophagus during deglutition.

As in other painful conditions, many patients with facial pain do not describe stereotypic syndromes. These patients have sometimes had their syndromes categorized as "atypical facial pain," as though this were a well-defined clinical entity. Only scant evidence shows that nondescript facial pain is caused by emotional distress, as is sometimes alleged. Vague, poorly localized, continuous facial pain is *characteristic* of the condition that may result from nasopharyngeal carcinoma and other somatic diseases; a burning painful element often supervenes as deafferentation occurs and evidence of cranial neuropathy appears. Occasionally, the cause of a pain problem cannot be promptly resolved, thus necessitating periodic follow-up examinations until further clues appear (and they usually do). *Facial pain of unknown cause* is a more reasonable tentative diagnosis than "atypical facial pain."

PAIN-SENSITIVE STRUCTURES OF THE HEAD

The most common type of pain results from activation of peripheral nociceptors in the presence of a normally functioning nervous system, as in the pain resulting from scalded skin or appendicitis. Another type of pain results from injury to or activation of the peripheral or central nervous system. Headache, formerly believed to originate peripherally, may originate from either mechanism. Headache may arise from dysfunction or displacement of, or encroachment on, pain-sensitive cranial structures. The following are sensitive to mechanical stimulation: the scalp and aponeurosis, middle meningeal artery, dural sinuses, falx cerebri, and the proximal segments of the large pial arteries. The ventricular ependyma, choroid plexus, pial veins, and much of the brain parenchyma are insensitive to pain. On the other hand, electrical stimulation near midbrain dorsal raphe cells may result in migrainelike headaches. Thus, most of the brain is insensitive to electrode probing, but a particular midbrain site is nevertheless a putative locus for headache generation.

Sensory stimuli from the head are conveyed to the brain by the trigeminal nerves from structures above the tentorium in the anterior and middle fossae of the skull. The first three cervical nerves carry stimuli from the posterior fossa and infradural structures. The ninth and tenth cranial nerves supply part of the posterior fossa and refer pain to the ear and throat.

Headache can occur as the result of the following:

1. Distention, traction, or dilation of intracranial or extracranial arteries,
2. Traction or displacement of large intracranial veins or their dural envelope,
3. Compression, traction, or inflammation of cranial and spinal nerves,
4. Spasm, inflammation, and trauma to cranial and cervical muscles,
5. Meningeal irritation and raised intracranial pressure,
6. Perturbation of intracerebral serotonergic projections.

By and large, intracranial masses cause headache when they deform, displace, or exert traction on vessels, dural structures, or cranial nerves at the base of the brain; these changes often happen long before intracranial pressure rises. Such mechanical displacement mechanisms do not explain headaches resulting from cerebral ischemia, benign intracranial hypertension after reduction of the pressure, or febrile illnesses and systemic lupus erythematosus. Impaired central inhibition as a result of perturbation of intracerebral serotonergic projections has been posited as a possible mechanism for these phenomena.

APPROACH TO THE PATIENT WITH HEADACHE

Entirely different diagnostic possibilities are raised by the patient who has the first severe headache ever and the one who has had recurrent headaches for many years. The probability of finding a potentially serious cause is considerably greater in patients with their first severe headache than in those with chronic recurrent headaches. Acute causes include meningitis, subarachnoid hemorrhage, epidural or subdural hematoma, glaucoma, and purulent sinusitis. In general, acute, severe headache with stiff neck and fever means meningitis, and without fever means subarachnoid hemorrhage; when the physician is confronted with such a patient, lumbar puncture is mandatory. Acute, persistent headache and fever are often manifestations of an acute systemic viral infection; if the neck is supple, lumbar puncture may be deferred. A first attack of migraine is always a possibility, but fever is a rare associated feature. Nearly all illnesses have been an occasional cause of headache; however, some illnesses are *characteristically* associated with headache. These include infectious mononucleosis, systemic lupus erythematosus, chronic pulmonary failure with hypercapnia (early morning headaches), Hashimoto thyroiditis, corticosteroid withdrawal, oral contraceptives, ovulation-promoting agents, inflammatory bowel disease, many illnesses associated with human immunodeficiency virus infection, and acute blood pressure elevation that occurs in pheochromocytoma and malignant hypertension. Pheochromocytoma and malignant hypertension are the exceptions to the generalization that hypertension *per se* is an uncommon cause of headache; a diastolic pressure of at least 120 mm Hg is requisite for hypertension to cause headache.

Adolescents with chronic daily frontal or holocephalic headache pose a special problem. Extensive diagnostic tests, including psychiatric assessment, are most often unrevealing. Fortunately, the headaches tend to stop after a few years, so that structured analgesic support can enable these teenagers to move through secondary school and enter college. By the time they reach their late teens, the cycle has usually ended.

The relationship of head pain to depression is not straightforward. Many patients in chronic daily pain cycles become depressed (a reasonable sequence of events); moreover, there is a greater-than-chance coincidence of migraine with both bipolar (manic-depressive) and unipolar depressive disorders. Studies of large populations of depressed patients do not reveal headache prevalence rates that are different from those in the general population. The physician should be cautious about assigning depression as the cause of recurring headache; drugs with antidepressant action are also effective in migraine.

Finally, note must be made of recurring headaches that may be pain-driven. As an example, *temporomandibular joint (TMJ) dysfunction* generally produces preauricular pain that is associated with chewing food. The pain may radiate to the head but is not easily confused with headache *per se*. Conversely, headache-prone patients may observe that headaches are more frequent and severe in the presence of a painful TMJ problem. Similarly, headache disorders may be activated by the pain attending otologic or endodontic surgical procedures. Treatment of such headaches is largely ineffectual until the cause of the primary pain is treated. Thus, pain about the head as a result of somatic disease or trauma may reawaken an otherwise quiescent migrainous mechanism.

CHAPTER 9. INVOLUNTARY MOVEMENTS

STANLEY FAHN

[Suggested Readings](#)

Although convulsions, fasciculations, and myokymia are involuntary movements, these disorders have special characteristics and are not classified with the types of abnormal involuntary movements described in this chapter. The disorders commonly called abnormal involuntary movements, or *dyskinesias*, are usually evident when a patient is at rest, are frequently increased by action, and disappear during sleep. There are exceptions to these generalizations. For example, palatal myoclonus may persist during sleep, and mild torsion dystonia may be present only during active voluntary movements (action dystonia), but not when the patient is at rest. The known dyskinesias are distinguished mainly by visual inspection of the patient. Electromyography can occasionally be helpful by determining the rate, rhythmicity, and synchrony of involuntary movements. Sometimes, patients have a dyskinesia that bridges the definitions of more than one disorder; this leads to compound terms such as choreoathetosis, which describes features of both chorea and athetosis.

Most abnormal involuntary movements are continual or easily evoked, but some are intermittent or paroxysmal, such as tics, the *paroxysmal dyskinesias*, and *episodic ataxias*. Gross movements of joints are highly visible, unlike the restricted muscle twitching of fasciculation or myokymia.

Tremors are rhythmic oscillatory movements. They result from alternating contractions of opposing muscle groups (e.g., parkinsonian tremor at rest) or from simultaneous contractions of agonist and antagonist muscles (e.g., essential tremor). A useful way to clinically differentiate tremor to aid in diagnosis is to determine whether the tremor is present under the following conditions: when the affected body part is at rest, as in parkinsonian disorders of the extrapyramidal system; when posture is maintained (e.g., with arms outstretched in front of the body), as in essential tremor (see [Chapter 113](#)); when action is undertaken (e.g., writing or pouring water from a cup), as in essential tremor, which increases with action; or when intention is present (e.g., finger-to-nose maneuver), as in cerebellar disease (see [Chapter 107](#)).

The term *myoclonus* (see [Chapter 110](#)) refers to shocklike movements due to contractions or inhibitions (negative myoclonus). *Chorea* delineates brief, irregular contractions that, although rapid, are not as lightninglike as myoclonic jerks. In classic choreic disorders, such as Huntington disease (see [Chapter 108](#)) and Sydenham chorea (see [Chapter 109](#)), the jerks affect individual muscles as random events that seem to flow from one muscle to another. They are not repetitive or rhythmic. *Ballism* is a form of chorea in which the choreic jerks are of large amplitude, producing flinging movements of the affected limbs. Chorea is presumably related to disorders of the caudate nucleus but sometimes involves other structures. Ballism is related to lesions of the subthalamic nucleus.

Dystonia (see [Chapter 112](#)) is a syndrome of sustained muscle contraction that frequently causes twisting and repetitive movements or abnormal postures. Dystonia is represented by (1) sustained contractions of both agonist and antagonist muscles, (2) an increase of these involuntary contractions when voluntary movement in other body parts is attempted ("overflow"), (3) rhythmic interruptions (*dystonic tremor*) of these involuntary, sustained contractions when the patient attempts to oppose them, (4) inappropriate or opposing contractions during specific voluntary motor actions (*action dystonia*), and (5) torsion spasms that may be as rapid as chorea but differ because the movements are continual and of a twisting nature in contrast to the random and seemingly flowing movements of chorea. Torsion spasms may be misdiagnosed as chorea; the other characteristics frequently lead to the misdiagnosis of a conversion reaction.

Tics are patterned sequences of coordinated movements that appear suddenly and intermittently. The movements are occasionally simple and resemble a myoclonic jerk, but they are usually complex, ranging from head shaking, eye blinking, sniffing, and shoulder shrugging to complex facial distortions, arm waving, touching parts of the body, jumping movements, or making obscene gestures (*copropraxia*). Most often, tics are rapid and brief, but occasionally they can be sustained motor contractions (i.e., dystonic). In addition to motor tics, vocalizations may be a manifestation of tics. These range from sounds, such as barking, throat-clearing, or squealing, to verbalization, including the utterance of obscenities (*coprolalia*) and the repetitions of one's own sounds (*palilalia*) or the sounds of others (*echolalia*). Motor and vocal tics are the essential features of Tourette syndrome (see [Chapter 111](#)).

One feature of tics is the compelling need felt by the patient to make the motor or phonic tic, with the result that the tic movement brings relief from unpleasant sensations that develop in the involved body part. Tics can be voluntarily controlled for brief intervals, but such a conscious effort is usually followed by more intense and frequent contractions. The milder the disorder is, the more control the patient can exert. Tics can sometimes be suppressed in public. The spectrum of severity and persistence of tics is wide. Sometimes, tics are temporary, and sometimes they are permanent.

Many persons develop personalized mannerisms. These physiologic tics may persist after repeated performances of motor habits and have therefore been called *habit spasms*. As a result, unfortunately, all tics have been considered by some physicians as habit spasms of psychic origin. Today, however, the trend is to consider pathologic tics a neurologic disorder.

Stereotypic movements (*stereotypies*) can resemble tics, but these are usually encountered in persons with mental retardation, autism, or schizophrenia. However, bursts of stereotypic shaking movements, especially of the arms, can be encountered in otherwise normal children. Stereotypic movements are also encountered in the syndrome of drug-induced tardive dyskinesia (see [Chapter 116](#)) and refer to repetitive movements that most often affect the mouth; in *orobuccolingual dyskinesia*, there are constant chewing movements of the jaw, writhing and protrusion movements of the tongue, and puckering movements of the mouth. Other parts of the body may also be involved.

Athetosis is a continuous, slow, writhing movement of the limbs (distal and proximal), trunk, head, face, or tongue. When these movements are brief, they merge with chorea (*choreoathetosis*). When the movements are sustained at the peak of the contractions, they merge with dystonia, and the term *athetotic dystonia* can be applied.

Akathitic movements are those of restlessness. They commonly accompany the subjective symptom of *akathisia*, an inner feeling of motor restlessness or the need to move. Today, akathisia is most commonly seen as a side effect of anti-psychotic drug therapy, either as acute akathisia or tardive akathisia, which often accompanies tardive dyskinesia. Akathitic movements (e.g., crossing and uncrossing the legs, caressing the scalp or face, pacing the floor, and squirming in a chair) can also be a reaction to stress, anxiety, boredom, or impatience; it can then be termed *physiologic* akathisia. Pathologic akathisia, in addition to that induced by antipsychotic drugs, can be seen in the encephalopathies of confusional states, in some dementias and in Parkinson disease. Picking at the bedclothes is a common manifestation of akathitic movements in bedridden patients.

Two other neurologic conditions in which there are subjective feelings of the need to move are *tics* and the *restless legs syndrome*. The latter is characterized by formication in the legs, particularly in the evening when the patient is relaxing and sitting or lying down and attempting to fall asleep. These sensations of ants crawling under the skin disappear when the patient walks around. This disorder is not understood but may respond to opioids, levodopa, and dopamine agonists.

Continued muscle stiffness due to continuous muscle firing can be the result of neuromyotonia, encephalomyelitis with rigidity and myoclonus (spinal interneuronitis), the stiff limb syndrome, and the stiff person syndrome (see [Chapter 129](#)). The last tends to involve axial and proximal limb muscles.

Paroxysmal movement disorders are syndromes in which the abnormal involuntary movements appear for brief periods out of a background of normal movement patterns. They can be divided into four distinct groups: (1) the *paroxysmal dyskinesias*, (2) *paroxysmal hypnogenic dyskinesias*, (3) *episodic ataxias*, and (4) *hyperekplexias*. The molecular genetics of the episodic ataxias implicate abnormalities of membrane ionic channels as underlying mechanisms for the paroxysmal movement disorders.

Three types of paroxysmal dyskinesias are recognized ([Table 9.1](#)). All three consist of bouts of any combination of dystonic postures, chorea, athetosis, and ballism. They can be unilateral, always on one side or on either side, or bilateral. Unilateral episodes can be followed by a bilateral one. The attacks can be severe enough to cause a patient to fall down. Speech is often affected, with inability to speak due to dystonia, but there is never any alteration of consciousness. Very often, patients report variable sensations at the beginning of the paroxysms. *Paroxysmal kinesigenic dyskinesia* is the easiest to recognize. Attacks are very brief, usually lasting seconds, and always less than 5 minutes. They are induced by sudden movements, startle, or hyperventilation, and can occur many times a day; they respond to anticonvulsants. The primary forms of paroxysmal dyskinesias are inherited in an autosomal-dominant pattern, but secondary causes are common, particularly

CHAPTER 10. SYNDROMES CAUSED BY WEAK MUSCLES

LEWIS P. ROWLAND

[Recognition of Weakness or Pseudoweakness](#)
[Patterns of Weakness](#)
[Suggested Readings](#)

Weakness implies that a muscle cannot exert normal force. Neurologists use the words *paralysis* or *plegia* to imply total loss of contractility; anything less than total loss is *paresis*. In practice, however, someone may mention a *partial hemiplegia*, which conveys the idea even if it is internally inconsistent. *Hemiplegia* implies weakness of an arm and leg on the same side. *Crossed hemiplegia* is a confusing term, generally implying unilateral cranial nerve signs and hemiplegia on the other side, a pattern seen with brainstem lesions above the decussation of the corticospinal tracts. *Monoplegia* is weakness of one limb; *paraplegia* means weakness of both legs.

This chapter describes syndromes that result from pathologically weak muscles, so that a student new to neurology can find the sections of the book that describe specific diseases. There is more than one approach to this problem, because no single approach is completely satisfactory. Elaborate algorithms have been devised, but the flowchart may be too complicated to be useful unless it is run by a computer.

It may be simpler to determine first whether there is pathologic weakness, then to find evidence of specific syndromes that depend on recognition of the following characteristics: distribution of weakness, associated neurologic abnormalities, tempo of disease, genetics, and patient age.

RECOGNITION OF WEAKNESS OR PSEUDOWEAKNESS

Patients with weak muscles do not often use the word “weakness” to describe their symptoms. Rather, they complain that they cannot climb stairs, rise from chairs, or run or that they note footdrop (and may actually use that term). They may have difficulty turning keys or doorknobs. If proximal arm muscles are affected, lifting packages, combing hair, or working overhead may be difficult. Weakness of cranial muscles causes ptosis of the eyelids, diplopia, dysarthria, dysphagia, or the cosmetic distortion of facial paralysis. These specific symptoms will be analyzed later.

Some people use the word “weakness” when there is no neurologic abnormality. For instance, aging athletes may find that they can no longer match the achievements of youth, but that is not pathologic weakness. Weakness in a professional athlete causes the same symptoms that are recognized by other people when the disorder interferes with the conventional activities of daily life. Losing a championship race, running a mile in more than 4 minutes, or jogging only 5 miles instead of a customary 10 miles are not symptoms of diseased muscles.

Others who lack the specific symptoms of weakness may describe “*chronic fatigue*.” They cannot do housework; they have to lie down to rest after the briefest exertion. If they plan an activity in the evening, they may spend the entire day resting in advance. Employment may be in jeopardy. Myalgia is a common component of this syndrome, and there is usually evidence of depression.

The chronic fatigue syndrome affects millions of people and is a major public health problem. Vast research investments have been made to evaluate possible viral, immune, endocrine, autonomic, metabolic, and other factors. None, however, seems as consistent as depression and psychosocial causes. It is not, as some put it, a “diagnosis of exclusion.” Instead, the characteristic history is recognizable, and on examination there is no limb weakness or reflex alteration.

Fading athletes and depressed, tired people with aching limbs have different emotional problems, but both groups lack the specific symptoms of muscle weakness, and they share two other characteristics: No abnormality appears on neurologic examination, and no true weakness is evident on manual muscle examination. That is, there is no weakness unless the examiner uses brute force. A vigorous young adult examiner may outwrestle a frail octogenarian, but that does not imply pathologic weakness in the loser. Students and residents must use reasonable force in tests of strength against resistance.

Fatigue and similar symptoms may sometimes be manifestations of systemic illness due to anemia, hypoventilation, congestive heart failure with hypoxemia and hypercapnia, cancer, or systemic infection. There is usually other evidence of the underlying disease, however, and that syndrome is almost never mistaken for a neurologic disorder.

Other patients have *pseudoweakness*. For instance, some patients attribute a gait disorder to weak legs, but it is immediately apparent on examination or even before formal examination that they have parkinsonism. Or a patient with peripheral neuropathy may have difficulty with fine movements of the fingers, not because of weakness but because of severe sensory loss. Or a patient may have difficulty raising one or both arms because of bursitis, not limb weakness. Or a patient with arthritis may be reluctant to move a painful joint. These circumstances are explained by findings on examination.

Examination may also resolve another problem in the evaluation of symptoms that might be due to weakness. Sometimes, when limb weakness is mild, it is difficult for the examiner to know how much resistance to apply to determine whether the apparent weakness is “real.” Then, the presence or absence of wasting, fasciculation, or altered tendon reflexes may give the crucial clues. Symptomatic weakness is usually accompanied by some abnormality on examination. Even in myasthenia gravis, symptoms may fluctuate in intensity, but there are always objective signs of abnormality on examination if the patient is currently having symptoms. There is a maxim: A normal neurologic examination is incompatible with the diagnosis of symptomatic myasthenia gravis.

Finally, examination may uncover patients with pseudoweakness that may be due to deceit, deliberate or otherwise. Hysterical patients and Munchausen deceivers or other malingerers who feign weakness all lack specific symptoms. Or they may betray inconsistencies in the history because they can participate in some activities but not in others that involve the same muscles. On examination, their dress, cosmetic facial makeup, and behavior may be histrionic. In walking, they may stagger dramatically, but they do not fall or injure themselves by bumping into furniture. In manual muscle tests, they abruptly give way, or they shudder in tremor rather than apply constant pressure. Misdirection of effort is one way to describe that behavior. Some simply refuse to participate in the test. The extent of disorder may be surprising, however. I and others have seen psychogenic impairment of breathing that led to use of a mechanical ventilator.

PATTERNS OF WEAKNESS

In analyzing syndromes of weakness, the examiner uses several sources of information for the differential diagnosis. The pattern of weakness and associated neurologic signs delimit some of the anatomic possibilities to answer the question of *where* the lesion is located. Patient age and the tempo of evolution aid in deciding *what* the lesion is.

The differential diagnosis of weakness encompasses much of clinical neurology, so the reader will be referred to other sections for some of the review. For instance, the first task in the analysis of a weak limb is to determine whether the condition is due to a lesion of the upper or lower motor neuron, a distinction that is made on the basis of clinical findings. Overactive tendon reflexes with clonus, Hoffmann signs, and Babinski signs denote an upper motor neuron disorder. Lower motor neuron signs include muscle weakness, wasting, and fasciculation, with loss of tendon reflexes. These distinctions may seem crude, but they have been passed as reliable from generation to generation of neurologists.

If the clinical signs imply a lower motor neuron disorder, the condition could be due to problems anywhere in the motor unit (motor neuron or axon, neuromuscular junction, or muscle). This determination is guided by principles stated in [Chapter 124](#). Diseases of the motor unit are also covered in that chapter, so the following information will be concerned primarily (but not entirely) with central lesions.

Hemiparesis

If there is weakness of the arm and leg on the same side and upper motor neuron signs imply a central lesion, the lesion could be in the cervical spinal cord or in the

brain. Pain in the neck or in the distribution of a cervical dermatome might be clues to the site of the lesion. Unilateral facial weakness may be ipsilateral to the hemiparesis, placing the lesion in the brain and above the nucleus of the seventh cranial nerve; or a change in mentation or speech may indicate that the lesion is cerebral, not cervical. Sometimes, however, there are no definite clinical clues to the site of the lesion, and the examiner must rely on magnetic resonance imaging (MRI), computed tomography (CT), electroencephalography, cerebrospinal fluid (CSF) findings, or myelography to determine the site and nature of the lesion together.

The course of hemiparesis gives clues to the nature of the disorder. The most common cause in adults is cerebral infarction or hemorrhage. Abrupt onset, prior transient attacks, and progression to maximal severity within 24 hours in a person with hypertension or advanced age are indications that a stroke has occurred. If no cerebral symptoms are present, there could conceivably be transverse myelitis of the cervical spinal cord, but that condition would be somewhat slower in evolution (days rather than hours) and more likely to involve all four limbs. Similarly, multiple sclerosis is more likely to be manifest by bilateral corticospinal signs than by a pure hemiplegia.

If hemiparesis of cerebral origin progresses for days or weeks, it is reasonable to suspect a cerebral mass lesion, whether the patient is an adult or a child. If the patient has had focal seizures, that possibility is the more likely. In addition to brain tumors, other possibilities include arteriovenous malformation, brain abscess, or other infections. Infectious or neoplastic complications of acquired immunodeficiency syndrome are constant considerations these days. Metabolic brain disease usually causes bilateral signs with mental obtundation and would be an unusual cause of hemiparesis, even in a child.

Hemiparesis of subacute evolution could arise in the cervical spinal cord if there were, for instance, a neurofibroma of a cervical root. That condition would be signified by local pain in most cases, and because there is so little room in the cervical spinal canal, bilateral corticospinal signs would probably be present.

In general, hemiparesis usually signifies a cerebral lesion rather than one in the neck, and the cause is likely to be denoted by the clinical course and by CT or MRI.

Paraparesis

Paresis means weakness, and *paraparesis* is used to describe weakness of both legs. The term has also been extended, however, to include gait disorders caused by lesions of the upper motor neuron, even when there is no weakness on manual muscle examination. The disorder is then attributed to *spasticity* or the clumsiness induced by malfunction of the corticospinal tracts. In adults, the most common cause of that syndrome, *spastic paraparesis of middle life*, is multiple sclerosis. The differential diagnosis includes tumors in the region of the foramen magnum, Chiari malformation, cervical spondylosis, arteriovenous malformation, and primary lateral sclerosis (all described in other sections of this book). The diagnosis cannot be made on clinical grounds alone and requires information from CSF examination (protein, cells, gamma globulin, oligoclonal bands), evoked potentials, CT, MRI, and myelography.

When there are cerebellar or other signs in addition to bilateral corticospinal signs, the disorder may be multiple sclerosis or an inherited disease, such as olivopontocerebellar degeneration. The combination of lower motor neuron signs in the arms and upper motor neuron signs in the legs is characteristic of amyotrophic lateral sclerosis; the same syndrome has been attributed without proof to cervical spondylosis. That pattern may also be seen in syringomyelia, but it is exceptional to find syringomyelia without typical patterns of sensory loss.

Other clues to the nature of spastic paraparesis include cervical or radicular pain in neurofibromas or other extraaxial mass lesions in the cervical spinal canal. Or there may be concomitant cerebellar signs or other indication of multiple sclerosis.

It is said that brain tumors in the parasagittal area may cause isolated spastic paraparesis by compressing the leg areas of the motor cortex in both hemispheres. This possibility seems more theoretical than real, however, because no well documented cases have been reported.

Chronic paraparesis may also be due to lower motor neuron disorders. Instead of upper motor neuron signs, there is flaccid paraparesis, with loss of tendon reflexes in the legs. This differential diagnosis includes motor neuron diseases, peripheral neuropathy, and myopathy as described in [Chapter 124](#).

Paraparesis of acute onset (days rather than hours or weeks) presents a different problem in diagnosis. If there is back pain and tendon reflexes are preserved or if there are frank upper motor neuron signs, a compressive lesion may be present. As the population ages, metastatic tumors become an increasingly more common cause. In children or young adults, the syndrome may be less ominous, even with pain, because the disorder is often due to acute transverse myelitis. This may be seen in children or adults, and in addition to the motor signs, a sensory level usually designates the site of the lesion. Spinal MRI or myelography is needed to make this differentiation. In the elderly population, a rare cause of acute paraplegia is infarction of the spinal cord. That syndrome is also sometimes seen after surgical procedures that require clamping of the aorta.

If the tendon reflexes are lost and there is no transverse sensory level in a patient with an acute paraparesis, the most common cause is Guillain-Barré syndrome, at any age from infancy to the senium. Sensory loss may facilitate that diagnosis, but sometimes little or no sensory impairment occurs. Then, the diagnosis depends on examination of the CSF and electromyography (EMG). The Guillain-Barré syndrome, however, may also originate from diverse causes. In developing countries, acute paralytic poliomyelitis is still an important cause of acute paraplegia. Rarely, an acute motor myelitis may be due to some other virus. In China, for instance, there have been summertime outbreaks of an acute motor axonopathy that differs from both Guillain-Barré syndrome and poliomyelitis, in particular, but, like the other syndromes, causes paraparesis.

The “reverse” of paraplegia would be weakness of the arms with good function in the legs, or *bibrachial paresis*. Lower motor neuron syndromes of this nature are seen in some cases of amyotrophic lateral sclerosis (with or without upper motor neuron signs in the legs). The arms hang limply at the side while the patient walks with normal movements of the legs. Similar patterns may be seen in some patients with myopathy of unusual distribution. It is difficult to understand how a cerebral lesion could cause weakness of the arms without equally severe weakness of the legs, but this “man-in-the-barrel syndrome” is seen in comatose patients who survive a bout of severe hypotension. The site of the lesion is not known, but it could be bilateral and prerolandic.

Monomelic Paresis

If one leg or one arm is weak, the presence of pain in the low back or the neck may point to a compressive lesion. Whether acute or chronic, herniated nucleus pulposus is high on the list of possibilities if radicular pain is present. Acute brachial plexus neuritis (neuralgic amyotrophy) is another cause of weakness in one limb with pain; a corresponding syndrome of the lumbosacral plexus is much less common. Peripheral nerve entrapment syndromes may also cause monomelic weakness and pain, but the pain is local, not radicular. Mononeuritis multiplex may also cause local pain, paresthesia, and paresis.

In painless syndromes of isolated limb weakness in adults, motor neuron disease is an important consideration if there is no sensory loss. Sometimes, in evaluating a limb with weak, wasted, and fasciculating muscle, the examiner is surprised because tendon reflexes are preserved or even overactive, instead of being lost. This apparent paradox implies lesions of both upper and lower motor neurons, almost pathognomonic of amyotrophic lateral sclerosis. The signs may be asymmetric in early stages of the disease.

Although rare, it is theoretically possible for strokes or other cerebral lesions to cause monomelic weakness with upper motor neuron signs. Weakness due to a cerebral lesion may be more profound in the arm, but abnormal signs are almost always present in the leg, too; that is, the syndrome is really a hemiparesis.

Neck Weakness

Difficulty holding up the head is seen in some patients with diseases of the motor unit, probably never in patients with upper motor neuron disorders. Usually, patients with neck weakness also have symptoms of disorder of the lower cranial nerves (dysarthria and dysphagia) and often also of adjacent cervical segments, as manifest by difficulty raising the arms. Amyotrophic lateral sclerosis and myasthenia gravis are probably the two most common causes.

Rarely, there is isolated weakness of neck muscles, with difficulty holding the head up, but no oropharyngeal or arm symptoms. This *floppy head syndrome* or *dropped head syndrome* is a disabling disorder that is usually due to one of three conditions: motor neuron disease, myasthenia gravis, or polymyositis. I have seen one such patient with a Chiari malformation. Some cases, however, are idiopathic.

New terms have been introduced to explain this syndrome: the bent spine syndrome and isolated myopathy of the cervical extensor muscles, which may be variations of the same condition. EMG shows a myopathic pattern in affected paraspinal muscles, and MRI may show replacement of muscle by fat in cervical, thoracic, or both areas.

Weakness of Cranial Muscles

The syndromes due to weakness of cranial muscles are reviewed in [Chapter 7](#) and [Chapter 68](#). The major problems in differential diagnosis involve the site of local lesions that affect individual nerves of ocular movement, facial paralysis, or the vocal cords. Pseudobulbar palsy due to upper motor neuron lesions must be distinguished from bulbar palsy due to lower motor neuron disease and then almost always a form of amyotrophic lateral sclerosis. This distinction depends on associated signs of upper or lower motor neuron lesions. Myasthenia gravis can affect the eyes, face, or oropharynx (but only exceptionally the vocal cords); in fact, the diagnosis of myasthenia gravis is doubtful if there are no cranial symptoms. Brainstem syndromes in the aging population may be due to stroke, meningeal carcinomatosis, or brainstem encephalitis.

Observation of the stance and gait of patients with neurologic symptoms can provide important diagnostic information and may immediately suggest particular disorders of motor or sensory function, or even specific diseases. Some types of gait are so characteristic of certain diseases that the diagnosis may be obvious at the initial encounter with a patient. An example of this is the typical posture and gait of patients with Parkinson disease.

In normal bipedal locomotion, one leg and then the other alternately supports the erect moving body. Each leg undergoes brief periods of acceleration and deceleration as body weight shifts from one foot to the other. When the moving body passes over the supporting leg, the other leg swings forward in preparation for its next support phase. One foot or the other constantly contacts the ground, and when support of the body is transferred from the trailing leg to the leading leg, both feet are on the ground momentarily.

Normal bipedal locomotion requires two processes: continuous ground reaction forces that support the body's center of gravity, and periodic movement of each foot from one position of support to the next in the direction of progression. As a consequence of these basic requirements, certain displacements of the body segments regularly occur in walking. To start walking, a person raises one foot and accelerates the leg forward; this is the *swing phase* of walking. Muscle action in the supporting leg causes the center of gravity of the body to move forward, creating a horizontal reaction force at the foot. The greater this reaction force is, the greater is the acceleration of the body, because the amount of force equals the body mass multiplied by the amount of acceleration. The swing phase ends when the leg that has swung forward makes contact with the ground, which is when the *stance phase* of walking begins. During the stance phase, the body weight shifts to the opposite leg and another swing phase can begin. The major groups of muscles of the leg are active at the beginning and the end of the stance and swing phases. As the body passes over the weight-bearing leg, it tends to be displaced toward the weight-bearing side, causing a slight side-to-side movement. In addition, the body rises and falls with each step. The body rises to a maximum level during the swing phase and descends to a minimum level during the stance phase. As the body accelerates upward during the swing phase, the vertical floor reaction increases to a value that exceeds the body weight. The vertical floor reaction falls to a minimum during downward acceleration, reducing the total vertical reaction to a value less than the body weight.

EXAMINING STANCE AND GAIT

When examining patients' stance and gait, the physician should observe them from the front, back, and sides. Patients should rise quickly from a chair, walk normally at a slow pace and then at a fast pace, and then turn around. They should walk successively on their toes, on their heels, and then in tandem (i.e., placing the heel of one foot immediately in front of the toes of the opposite foot and attempting to progress forward in a straight line). They should stand with their feet together and the head erect, first with open eyes and then with closed eyes, to determine whether they can maintain their balance.

When a person walks normally, the body should be held erect with the head straight and the arms hanging loosely at the sides, each moving rhythmically forward with the opposite leg. The shoulders and hips should be approximately level. The arms should swing equally. The steps should be straight and about equal in length. The head should not be tilted, and there should be no appreciable scoliosis or lordosis. With each step, the hip and knee should flex smoothly, and the ankle should dorsiflex with a barely perceptible elevation of the hips as the foot clears the ground. The heel should strike the ground first, and the weight of the body should be transferred successively onto the sole of the foot and then onto the toes. The head and then the body should rotate slightly with each step, without lurching or falling.

Although there are gross similarities in the way that normal people walk, each person walks in a distinctive fashion. The distinctions between people reflect both their individual physical characteristics and their personality traits. Among the variables that compose the physical characteristics are speed, stride length, positions of the feet (e.g., with the toes pointing outward or pointing inward), characteristics of the walking surface, and the type of footwear worn. Perhaps, more important are the goals to be accomplished in walking, as well as the person's aspirations, motivations, and attitudes. For some situations, speed is the most important factor. In other situations, safe arrival or the minimal expenditure of energy may be more important. Some people learn to walk gracefully or in the least obtrusive manner possible and consequently may expend extra energy. Others learn to walk ungracefully but as effectively as possible for the amount of energy expended. The manner of walking may provide clues to personality traits (e.g., aggressiveness, timidity, self-confidence, aloofness).

GAIT IN HEMIPARESIS

Hemiparesis from an upper motor neuron lesion results in a characteristic posture and gait owing to the combined effects of spasticity and weakness of the affected limbs. Patients with hemiparesis usually stand and walk with the affected arm flexed and the leg extended. In walking, they have difficulty flexing the hip and knee and dorsiflexing the ankle; the paretic leg swings outward at the hip to avoid scraping the foot on the floor. The leg maintains a stiff posture in extension and rotates in a semicircle, first away from and then toward the trunk, with a circumduction movement. Despite the circumduction, the foot may scrape the floor so that the toe and outer side of the sole of the shoe become worn first. The upper body often rocks slightly to the opposite side during the circumduction movement. The arm on the hemiparetic side usually moves little during walking, remaining adducted at the shoulder, flexed at the elbow, and partially flexed at the wrist and fingers. In a person without a previous motor disorder, loss of the swinging motion of an arm may be the first sign of a progressive upper motor neuron lesion that will result in a hemiparesis.

GAIT IN PARAPARESIS

Paraparesis usually results from lesions of the thoracic portion of the spinal cord. The gait of these patients results from the combined effects of spasticity and weakness of the legs and consists of slow, stiff movements at the knees and hips with evidence of considerable effort. The legs are usually maintained extended or slightly flexed at the hips and knees and are often adducted at the hips. In some patients, particularly those with severe spasticity, each leg may cross in front of the other during the swing phase of walking, causing a *scissors gait*. The steps are short, and patients may move the trunk from side to side in attempts to compensate for the slow, stiff movements of the legs. The legs circumduct at the hips, and the feet scrape the floor, so that the soles of the shoes become worn at the toes.

GAIT IN PARKINSONISM

The gait in Parkinson disease reflects a combination of akinesia (difficulty in initiating movement), dystonia (relatively fixed abnormal postures), rigidity, and tremor. These patients stand in a posture of general flexion, with the spine bent forward, the head bent downward, the arms moderately flexed at the elbows, and the legs slightly flexed. They stand immobile and rigid, with a paucity of automatic movements of the limbs and a masklike fixed facial expression with infrequent blinking. Although the arms are held immobile, often a rest tremor involves the fingers and wrists at 4 to 5 cycles per second. When these patients walk, the trunk bends even farther forward; the arms remain immobile at the sides of the body or become further flexed and carried somewhat ahead of the body. The arms do not swing. As patients walk forward, the legs remain bent at the knees, hips, and ankles. The steps are short so that the feet barely clear the ground and the soles of the feet shuffle and scrape the floor. The gait, with characteristically small steps, is termed *marche à petits pas*. Forward locomotion may lead to successively more rapid steps, and the patient may fall unless assisted; this increasingly rapid walking is called *festination*. If patients are pushed forward or backward, they cannot compensate with flexion or extension movements of the trunk. The result is a series of propulsive or retropulsive steps. Parkinsonian patients can sometimes walk with surprising rapidity for brief intervals. These patients often have difficulty when they start to walk after standing still or sitting in a chair. They may take several very small steps

that cover little distance before taking longer strides. The walking movements may stop involuntarily, and the patient may freeze on attempts to pass through a doorway or into an elevator.

GAIT IN CEREBELLAR DISEASE

Patients with disease of the cerebellum stand with their legs farther apart than normal and may develop *titubation*, a coarse fore-and-aft tremor of the trunk. Often, they cannot stand with their legs so close that the feet are touching; they sway or fall in attempts to do so, whether their eyes are open or closed. They walk cautiously, taking steps of varying length, some shorter and others longer than usual. They may lurch from one side to another. Because of this unsteady or *ataxic gait*, which they usually attribute to poor balance, they fear walking without support and tend to hold onto objects in the room, such as a bed or a chair, moving cautiously between these objects. When gait ataxia is mild, it can be enhanced by asking the patient to attempt tandem walking in a straight line, successively placing the heel of one foot directly in front of the toes of the opposite foot. Patients commonly lose their balance during this task and must quickly place one foot to the side to avoid falling.

When disease is restricted to the vermal portions of the cerebellum, disorders of stance and gait may appear without other signs of cerebellar dysfunction, such as limb ataxia or nystagmus. This pattern is seen in alcoholic cerebellar degeneration. Diseases of the cerebellar hemispheres, unilateral or bilateral, may also affect gait. With a unilateral cerebellar-hemisphere lesion, ipsilateral disorders of posture and movement accompany the gait disorder. Patients usually stand with the shoulder on the side of the lesion lower than the other; there is accompanying scoliosis. The limbs on the side of the cerebellar lesion show decreased resistance to passive manipulation (*hypotonia*). When these patients attempt to touch their nose and then the examiner's finger (the finger-nose-finger test), they miss their target and experience a side-to-side tremor generated from the shoulder. When they attempt to touch the knee of one leg with the heel of the other leg and then move the heel smoothly down along the shin (the heel-knee-shin test), a side-to-side tremor of the moving leg develops, generated from the hip. On walking, patients with cerebellar disease show ataxia of the leg ipsilateral to the cerebellar lesion; consequently they stagger and progressively deviate to the affected side. This can be demonstrated by asking them to walk around a chair. As they rotate toward the affected side, they tend to fall into the chair; rotating toward the normal side, they move away from the chair in a spiral. Patients with bilateral cerebellar-hemisphere disease show a disturbance of gait similar to that seen in disease of the vermis, but signs of cerebellar dysfunction also appear in coordinated limb movements. Thus, these patients show abnormal finger-nose-finger and heel-knee-shin tests bilaterally.

GAIT IN SENSORY ATAXIA

Another characteristic gait disorder results from loss of proprioceptive sensation in the legs due to lesions of the afferent fibers in peripheral nerves, dorsal roots, dorsal columns of the spinal cord, or medial lemnisci. Patients with such lesions are unaware of the position of the limbs and consequently have difficulty standing or walking. They usually stand with their legs spread widely apart. If asked to stand with their feet together and eyes open, they remain stable, but when they close their eyes, they sway and often fall (*Romberg sign*). They walk with their legs spread widely apart, watching the ground carefully. In stepping, they lift the legs higher than normal at the hips and fling them abruptly forward and outward. The steps vary in length and may cause a characteristic slapping sound as the foot contacts the floor. They usually hold the body somewhat flexed, often using a cane for support. If vision is impaired and these patients attempt to walk in the dark, the gait disturbance worsens.

PSYCHOGENIC GAIT DISORDERS

Psychogenic disorders of gait often appear in association with many other neurologic complaints, including "dizziness," loss of balance, and weakness of both legs or the arm and leg on one side of the body. The gait is usually bizarre, easily recognized, and unlike any disorder of gait evoked by organic disease. In some patients, however, hysteric gait disorders may be difficult to identify. The key to the diagnosis is the demonstration that objective organic signs of disease are missing. In hysteric hemiplegia, patients drag the affected leg along the ground behind the body and do not circumduct the leg, scraping the sole of the foot on the floor, as in hemiplegia due to an organic lesion. At times, the hemiplegic leg may be pushed ahead of the patient and used mainly for support. The arm on the affected side does not develop the flexed posture commonly seen with hemiplegia from organic causes, and the hyperactive tendon reflexes and Babinski sign on the hemiplegic side are missing.

Hysteric paraplegic patients usually walk with one or two crutches or lie helplessly in bed with the legs maintained in rigid postures or at times completely limp. The term *astasia-abasia* refers to patients who cannot stand or walk but who can carry out natural movements of the limbs while lying in bed. At times, patients with hysteric gait disorders walk only with seemingly great difficulty, but they show normal power and coordination when lying in bed. On walking, patients cling to the bed or objects in the room. If asked to walk without support, they may lurch dramatically while managing feats of extraordinary balance to avoid falling. They may fall, but only when a nearby physician or family member can catch them or when soft objects are available to cushion the fall. The gait disturbance is often dramatic, with the patient lurching wildly in many directions and finally falling, but only when other people are watching the performance. They often demonstrate remarkable agility in their rapid postural adjustments when they attempt to walk.

GAIT IN CEREBRAL PALSY

The term *cerebral palsy* includes several different motor abnormalities that usually result from perinatal injury. The severity of the gait disturbance varies, depending on the nature of the lesion. Mild limited lesions may result in exaggerated tendon reflexes and extensor plantar responses with a slight degree of talipes equinovarus but no clear gait disorder. More severe and extensive lesions often result in bilateral hemiparesis; patients stand with the legs adducted and internally rotated at the hips, extended or slightly flexed at the knees, with plantar flexion at the ankles. The arms are held adducted at the shoulders and flexed at the elbows and wrists. Patients walk slowly and stiffly with plantar flexion of the feet, causing them to walk on the toes. Bilateral adduction of the hips causes the knees to rub together or to cross, causing a scissors gait.

The gait in patients with cerebral palsy can be altered by movement disorders. Athetosis is common and consists of slow, serpentine movements of the arms and legs between the extreme postures of flexion with supination and extension with pronation. On walking, patients with athetotic cerebral palsy show involuntary limb movements that are accompanied by rotatory movements of the neck and constant grimacing. The limbs usually show the bilateral hemiparetic posture described previously; however, superimposed on this posture may be partially fixed asymmetric limb postures with, for example, flexion with supination of one arm and extension with pronation of the other. Asymmetric limb postures commonly occur in association with rotated postures of the head, generally with extension of the arm on the side to which the chin rotates and flexion of the opposite arm.

GAIT IN CHOREA

Chorea literally means the dance and refers to the gait disorder seen most often in children with Sydenham chorea or adults with Huntington disease. Both conditions are characterized by continuous and rapid movements of the face, trunk, and limbs. Flexion, extension, and rotatory movements of the neck occur with grimacing movements of the face, twisting movements of the trunk and limbs, and rapid piano-playing movements of the digits. Walking generally accentuates these movements. In addition, sudden forward or sideward thrusting movements of the pelvis and rapid twisting movements of the trunk and limbs result in a gait resembling a series of dancing steps. With walking, patients speed up and slow down at unpredictable times, evoking a lurching gait.

GAIT IN DYSTONIA MUSCULORUM DEFORMANS

The first symptom of this disorder often consists of an abnormal gait resulting from inversion of one foot at the ankle. Patients walk initially on the lateral side of the foot; as the disease progresses, this problem worsens, and other postural abnormalities develop, including elevation of one shoulder and hip and twisted postures of the trunk. Intermittent spasms of the trunk and limbs then interfere with walking. Eventually, there is torticollis, tortipelvis, lordosis, or scoliosis. Finally, patients may become unable to walk.

GAIT IN MUSCULAR DYSTROPHY

In muscular dystrophy, weakness of the muscles of the trunk and the proximal parts of the legs produces a characteristic stance and gait. In attempting to rise from the seated position, patients flex the trunk at the hips, put their hands on their knees, and push the trunk upward by working their hands up the thighs. This sequence of movements is termed *Gowers sign*. Patients stand with exaggerated lumbar lordosis and a protuberant abdomen because of weakness of the abdominal and

paravertebral muscles. They walk with the legs spread widely apart, showing a characteristic waddling motion of the pelvis that results from weakness of the gluteal muscles. The shoulders often slope forward, and winging of the scapulae may be seen as the patients walk.

SENILE GAIT DISORDERS

Many disorders of gait have been observed in elderly persons, including some people who have overt neurologic disease.

Cautious Gait

This gait is often seen in normal elderly people. It is characterized by a slightly widened base, shortened stride, slowness of walking, and turning in a block. There is no hesitancy in the initiation of gait and no shuffling or freezing. The rhythm of walking and foot clearance are normal. There is mild disequilibrium in response to a push and difficulty in balancing on one foot.

Subcortical Disequilibrium

This gait disorder is seen with progressive supranuclear palsy and multiinfarct dementia. Patients have marked difficulty maintaining the upright posture and show absent or poor postural adjustments in response to perturbations. Some patients hyperextend the trunk and neck and fall backward or forward, thus impairing locomotion. These patients commonly show ocular palsies, dysarthria, and the parkinsonian signs of rigidity, akinesia, and tremor.

Frontal Disequilibrium

Many patients with frontal disequilibrium cannot rise, stand, or walk; some cannot even sit without support. Standing and walking are difficult or impossible. When they try to rise from a chair, they lean backward rather than forward, and they cannot bring their legs under their center of gravity. When they attempt to step, their feet frequently cross and move in a direction that is inappropriate to their center of gravity. Clinical examination usually reveals dementia, signs of frontal release (suck, snout, and grasp reflexes), motor perseveration, urinary incontinence, pseudobulbar palsy, exaggerated muscle stretch reflexes, and extensor plantar responses.

Isolated Gait Ignition Failure

Patients with this disorder have difficulty starting to walk and continuing walking, even though they have no impairment of equilibrium, cognition, limb praxis, or extrapyramidal function. Once they start to walk, the steps are short and their feet barely clear the ground, thereby creating a shuffling appearance. With continued stepping, however, the stride lengthens, foot clearance is normal, and the arms swing normally. If their attention is diverted, their feet may freeze momentarily and shuffling may recur. Postural responses and stance base are normal, and falls are rare. The terms *magnetic gait* or *apraxia of gait* pertain to both isolated gait ignition failure and frontal gait disorder.

Frontal Gait Disorder

This disturbance is often seen with multiinfarct dementia or normal pressure hydrocephalus. Characteristically, these patients stand on a wide base (though sometimes a narrow base) and take short steps with shuffling, hesitate in starting to walk and in turning, and show moderate disequilibrium. Associated findings include cognitive impairment, pseudobulbar palsy with dysarthria, signs of frontal release (e.g., suck, snout, and grasping reflexes), paratonia, signs of corticospinal tract disease, and urinary dysfunction. In patients who have this gait disorder in association with normal pressure hydrocephalus, ventricular shunting may restore a normal gait.

GAIT IN LOWER MOTOR NEURON DISORDERS

Diseases of the motor neurons or peripheral nerves characteristically cause distal weakness, and footdrop is a common manifestation. In motor neuron disease and in the hereditary neuropathies (e.g., Charcot-Marie-Tooth disease), the disorder is likely to be bilateral. If the patient has a compressive lesion of one peroneal nerve, the process may be unilateral. In either case, patients cannot dorsiflex the foot in walking, as is normal each time the swinging leg begins to move. As a result, the toes are scuffed along the ground. To avoid this awkwardness, patients raise the knee higher than usual, resulting in a "steppage" gait. If the proximal muscles of the legs are affected (in addition to or instead of distal muscles), the gait also has a waddling appearance.

CHAPTER 12. SIGNS AND SYMPTOMS IN NEUROLOGIC DIAGNOSIS

LEWIS P. ROWLAND

[Patient Age](#)
[Sex](#)
[Ethnicity](#)
[Socioeconomic Considerations](#)
[Tempo of Disease](#)
[Duration of Symptoms](#)
[Medical History](#)
[Identifying the Site of Disorder](#)
[Suggested Readings](#)

An anonymous sage once said that 90% of the neurologic diagnosis depends on the patient's medical history and that the remainder comes from the neurologic examination and laboratory tests. Sometimes, of course, findings in blood tests, magnetic resonance imaging (MRI), or computed tomography (CT) are pathognomonic, but students have to learn which tests are appropriate and when to order them. It is therefore necessary to know which diagnostic possibilities are reasonable considerations for a particular patient. In the consideration of these different diagnostic possibilities, specific symptoms are not the only ingredient in the analysis of a patient's history, as this chapter briefly reviews.

It is commonly taught that neurologic diagnosis depends on answers to two questions that are considered separately and in sequence:

1. *Where is the lesion?* Is it in the cerebrum, basal ganglia, brainstem, cerebellum, spinal cord, peripheral nerves, neuromuscular junction, or muscle?
2. *What is the nature of the disease?*

If the site of the lesion can be determined, the number of diagnostic possibilities is reduced to a manageable number. An experienced clinician, however, is likely to deal with both questions simultaneously; site and disease are identified at the same time. Sometimes, the process is reversed. To take an obvious example, if a patient suddenly becomes speechless or awakens with a hemiplegia, the diagnosis of stroke is presumed. The location is then deduced from findings on examination, and both site and process are ascertained by CT or MRI. If there are no surprises in the imaging study (e.g., demonstration of a tumor or vascular malformation), further laboratory tests might be considered to determine the cause of an ischemic infarct.

The specific nature of different symptoms and findings on examination are reviewed in preceding chapters and in teaching manuals on the neurologic examination. Other considerations that influence diagnosis are briefly described here.

PATIENT AGE

The symptoms and signs of a stroke may be virtually identical in a 10-year-old, a 25-year-old, and a 70-year-old; however, the diagnostic implications are vastly different for each patient. Some brain tumors are more common in children, and others are more common in adults. Progressive paraparesis is more likely to be due to spinal cord tumor in a child, whereas in an adult it is more likely to be due to multiple sclerosis. Focal seizures are less likely to be fixed in pattern and are less likely to indicate a specific structural brain lesion in a child than in an adult. Myopathic weakness of the legs in childhood is more likely to be caused by muscular dystrophy than polymyositis; the reverse is true in patients older than 25 years. Muscular dystrophy rarely begins after age 35. Multiple sclerosis rarely starts after age 55. Hysteria is not a likely diagnosis when neurologic symptoms start after age 50. (These ages are arbitrary, but the point is that age is a consideration in some diagnoses.)

SEX

Only a few diseases are sex-specific. X-linked diseases (e.g., Duchenne muscular dystrophy) occur only in boys or, rarely, in girls with chromosome disorders. Among young adults, autoimmune diseases are more likely to affect women, especially systemic lupus erythematosus and myasthenia gravis, although young men are also affected in some cases. Women are exposed to the neurologic complications of pregnancy and may be at increased risk of stroke because of oral contraceptives. Men are more often exposed to head injury.

ETHNICITY

Stating the race of the patient in every case history is an anachronism of modern medical education. In neurology, race is important only when sickle cell disease is considered. Malignant hypertension and sarcoidosis may be more prevalent in blacks, but whites are also susceptible. Other ethnic groups, however, are more susceptible to particular diseases: Tay-Sachs disease, familial dysautonomia, and Gaucher disease in Ashkenazi Jews; thyrotoxic periodic paralysis in Japanese and perhaps in other Asians; nasopharyngeal carcinoma in Chinese; Marchiafava-Bignami disease in Italian wine drinkers (a myth?); and hemophilia in descendants of the Romanovs. Ethnicity is rarely important in diagnosis.

SOCIOECONOMIC CONSIDERATIONS

In general, social deprivation leads to increased mortality, and the reasons are not always clear. Ghetto dwellers, whatever their race, are prone to the ravages of alcoholism, drug addiction, and trauma. Impoverishment is also accompanied by malnutrition, infections, and the consequences of medical neglect. Within the ghetto and in other social strata, the acquired immunodeficiency syndrome epidemic has generated concern about the risk factors of male homosexuals, intravenous drug users, prostitutes, and recipients of blood transfusions. For most other neurologic disorders, however, race, ethnicity, sex, sexual orientation, and socioeconomic status do not affect the incidence.

TEMPO OF DISEASE

Seizures, strokes, and syncope are all abrupt in onset but differ in manifestations and duration. Syncope is the briefest. There are usually sensations that warn of the impending loss of consciousness. After fainting, the patient begins to recover consciousness in a minute or so. A seizure may or may not be preceded by warning symptoms. It can be brief or protracted and is manifested by alteration of consciousness or by repetitive movements, stereotyped behavior, or abnormal sensations. A stroke due to cerebral ischemia or hemorrhage "strikes out of the blue" and is manifest by hemiparesis or other focal brain signs. The neurologic disorder that follows brain infarction may be permanent, or the patient may recover partially or completely in days or weeks. If the signs last less than 24 hours, the episode is called a transient ischemic attack (TIA). Sometimes, it is difficult to differentiate a TIA from the postictal hemiparesis of a focal motor seizure, especially if the seizure was not witnessed. Another syndrome of abrupt onset is subarachnoid hemorrhage, in which the patient often complains of "the worst headache of my life;" this is sometimes followed by loss of consciousness.

Symptoms of less than apoplectic onset may progress for hours (intoxication, infection, or subdural hematoma), days (Guillain-Barré syndrome), or longer (most tumors of the brain or spinal cord). The acute symptoms of increased intracranial pressure or brain herniation are sometimes superimposed on the slower progression of a brain tumor. Progressive symptoms of brain tumor may be punctuated by seizures. Heritable or degenerative diseases tend to progress slowly, becoming most severe only after years of increasing disability (e.g., Parkinson disease or Alzheimer disease).

Remissions and exacerbations are characteristic of myasthenia gravis, multiple sclerosis, and some forms of peripheral neuropathy. Bouts of myasthenia tend to last for weeks at a time; episodes in multiple sclerosis may last only days in the first attacks and then tend to increase in duration and to leave more permanent neurologic disability. These diseases sometimes become progressively worse without remissions.

The symptoms of myasthenia gravis vary in a way that differs from any other disease. The severity of myasthenic symptoms may vary from minute to minute. More

often, however, there are differences in the course of a day (usually worse in the evening than in the morning, but sometimes vice versa) or from day to day.

Some disorders characteristically occur in bouts that usually last minutes or hours, rarely longer. Periodic paralysis, migraine headache, cluster headaches, and narcolepsy are examples of such disorders.

To recognize the significance of these differences in tempo, it is necessary to have some notion of the different disorders.

DURATION OF SYMPTOMS

It may be of diagnostic importance to know how long the patient has had symptoms before consulting a physician. Long-standing headache is more apt to be a tension or vascular headache, but headache of recent onset is likely to imply intracranial structural disease and should never be underestimated. Similarly, seizures or drastic personality change of recent onset implies the need for CT, MRI, and other studies to evaluate possible brain tumor or encephalopathy. If no such lesion is found or if seizures are uncontrolled for a long time, perhaps video-electroencephalographic monitoring should be carried out to determine the best drug therapy or surgical approach.

MEDICAL HISTORY

It is always important to know whether any systemic disease is in the patient's background. Common disorders, such as hypertensive vascular disease or diabetes mellitus, may be discovered for the first time when the patient is examined because of neurologic symptoms. Because they are common, these two disorders may be merely coincidental, but depending on the neurologic syndrome, either diabetes or hypertension may actually be involved in the pathogenesis of the neural signs. If the patient is known to have a carcinoma, metastatic disease is assumed to be the basis of neurologic symptoms until proved otherwise. If the patient is taking medication for any reason, the possibility of intoxication must be considered. Cutaneous signs may point to neurologic complications of von Recklinghausen disease or other phakomatoses or may suggest lupus erythematosus or some other systemic disease.

IDENTIFYING THE SITE OF DISORDER

Aspects of the history may suggest the nature of the disorder; specific symptoms and signs suggest the site of the disorder. *Cerebral disease* is implied by seizures or by focal signs that can be attributed to a particular area of the brain; hemiplegia, aphasia, or hemianopia are examples. Generalized manifestations of cerebral disease are seizures, delirium, and dementia. *Brainstem disease* is suggested by cranial nerve palsies, cerebellar signs of ataxia of gait or limbs, tremor, or dysarthria. Dysarthria may be due to incoordination in disorders of the cerebellum itself or its brainstem connections. Cranial nerve palsies or the neuromuscular disorder of myasthenia gravis may also impair speech. Ocular signs have special localizing value. Involuntary movements suggest *basal ganglia disease*.

Spinal cord disease is suggested by spastic gait disorder and bilateral corticospinal signs with or without bladder symptoms. If there is neck or back pain, a compressive lesion should be suspected; if there is no pain, multiple sclerosis is likely. The level of a spinal compressive lesion is more likely to be indicated by cutaneous sensory loss than by motor signs. The lesion that causes spastic paraparesis may be anywhere above the lumbar segments.

Peripheral nerve disease usually causes both motor and sensory symptoms (e.g., weakness and loss of sensation). The weakness is likely to be more severe distally, and the sensory loss may affect only position or vibration sense. A more specific indication of peripheral neuropathy is loss of cutaneous sensation in a glove-and-stocking distribution.

Neuromuscular disorders and diseases of muscle cause limb or cranial muscle weakness without sensory symptoms. If limb weakness and loss of tendon jerks are the only signs (with no sensory loss), electromyography and muscle biopsy are needed to determine whether the disorder is one of motor neurons, peripheral nerve, or muscle.

The diseases that cause these symptoms and signs are described later in this volume.

SECTION II. HOW TO SELECT DIAGNOSTIC TESTS

CHAPTER 13. COMPUTED TOMOGRAPHY AND MAGNETIC RESONANCE IMAGING

ROBERT DELAPAZ AND STEPHEN CHAN

[Computed Tomography](#)
[Magnetic Resonance Imaging](#)
[Uses of Computed Tomography](#)
[Uses of Magnetic Resonance Imaging](#)
[Paradigm: Diagnostic Workup for Stroke](#)
[Suggested Readings](#)

Computed tomography (CT) and magnetic resonance imaging (MRI) are the core imaging methods in neurodiagnosis. CT is quicker and less expensive, but MRI is now the “gold standard” for detecting and delineating intracranial and spinal lesions. Given the advances in MR technology, including magnetic resonance angiography (MRA), MR spectroscopy (MRS), and functional MRI, the usefulness of MRI will continue to grow. CT technology has also advanced. For instance, spiral or helical CT now permits scanning an entire body part, such as the neck, in less than 1 minute; it also makes CT suitable for angiographic and dynamic studies. In the past, the major advantage of CT was the speed of imaging, which reduced patient discomfort and motion artifact. New ultrafast MR methods such as echo-planar imaging (EPI) are now bringing MRI into the same arena.

COMPUTED TOMOGRAPHY

CT is based on image reconstruction from sets of quantitative x-ray measurements through the head from multiple angles. A fan beam of x-rays emitted from a single source passes through the head to an array of detectors. The x-ray source rotates around the patient's head, and the x-ray attenuation through the section plane is measured in compartments called pixels. The computer reconstructs the image from about 800,000 measurements and assigns a number to each pixel according to its x-ray attenuation (which is proportional to tissue electron density). These values are displayed along a gray scale from black for low density (low attenuation) to white for high density. Iodinated water-soluble contrast agents, which have high x-ray density, can be given intravenously to enhance differences in tissue density, show vascular structures, or detect areas of blood–brain barrier breakdown. CT differentiates between white and gray matter, shows the main divisions of the basal ganglia and thalamus and, after infusion of a contrast agent, depicts the major arteries and veins. CT is especially useful for identifying acute hemorrhage, which appears as much higher density than normal brain or cerebrospinal fluid (CSF).

A scanner gantry houses the x-ray source and detectors; it can be tilted to perform scans at a range of angles from axial to coronal, depending on head position, but not in the sagittal plane. Scan time can be shortened to less than 1 second to minimize motion artifact if the patient is restless. The major limitation of CT is in the posterior fossa, where linear artifacts appear because bone selectively attenuates the x-ray beam; the resulting “beam hardening” creates dense or lucent streaks that project across the brainstem and may obscure underlying lesions.

MAGNETIC RESONANCE IMAGING

A magnetic field causes alignment of atomic nuclei, such as hydrogen protons, into one of two (or more) magnetic states. In proton-based MRI, radiowaves (the radiofrequency pulse) are applied at a frequency that resonates with the hydrogen nucleus in tissue water, resulting in a shift of a small percentage of protons into higher energy states. Following the radiofrequency pulse, relaxation of these protons back to their original energy state is accompanied by the emission of radiowave signals that are characteristic of the particular tissue. Two tissue-specific relaxation-time constants are important. T1 is the longer time constant, generally from 500 to 2,000 milliseconds in the brain, and is a measure of the rate of proton reorientation back along the Z-axis of the magnetic field. T2 is the shorter time constant, usually 40 to 100 milliseconds in the brain, and is a measure of the interaction of protons during the relaxation process. The differences in tissue T1 and T2 relaxation times enable MRI to distinguish between fat, muscle, bone marrow, and gray or white matter of the brain. Most lesions in the brain prolong these relaxation times by increasing the volume or changing the magnetic properties of tissue water.

MR images are displayed as maps of tissue signal intensity values. Spatial localization is achieved by application of a magnetic field gradient across the magnet bore, creating slight variations in radiofrequency across the object being imaged. The specific location of the radiowave emissions can be determined by measurement of the exact radiofrequency. In addition, MR images can be modified for T1 or T2 relaxation characteristics or proton-density characteristics. Factors that influence the results include (1) the imaging technique or pulse sequence (e.g., spin echo, gradient echo, or inversion recovery), (2) the repetition time (the interval between repeated pulse sequences), and (3) the echo time (the interval between radiofrequency excitation and measurement of the radiowave emission or signal). T1-weighted images are most useful for depicting anatomy and show CSF and most lesions as low signal, except for areas of fat, subacute hemorrhage, or gadolinium (Gd) enhancement, which appear as high signal. T2-weighted images are more sensitive for lesion detection and show CSF and most lesions as high signal, except areas of acute hemorrhage or chronic hemosiderin deposits, which appear as low signal. Proton-density images show mixed contrast characteristics, reflecting both T1 and T2 weighting. All three types of images show rapidly flowing blood, dense calcification, cortical bone, and air as signal voids because of flow effects or absence of protons.

The most useful basic MRI technique is the *spin-echo* (SE) pulse sequence, which repeats the sequence of 90- and 180-degree pulses and measures the signal after each 180-degree pulse. The 90-degree pulse creates the radiowave perturbation of the tissue, and the following 180-degree pulse rephases the signal to produce an “echo,” which is the signal used for image reconstruction. A double SE method allows both proton-density and T2-weighted images to be obtained at the same time. *Fast spin-echo* (FSE) methods have reduced 8- to 10-minute acquisition times to 2 to 3 minutes for high-resolution images through the entire brain. The addition of an *inversion* 180-degree pulse before the 90-degree pulse, timed to suppress CSF signal, results in the fluid-attenuated inversion recovery (FLAIR) pulse sequence. FLAIR images are T2-weighted with low-signal CSF and are more sensitive in detecting lesions than SE or FSE pulse sequences. Gradient-echo (GRE) images are created by angles of less than 90 degrees without the 180-degree pulse; gradient switching generates the signal echoes. GRE imaging allows fast acquisition and is useful for detecting subtle magnetic field variations around hemorrhage; it is used primarily for specialized applications, such as MRA.

USES OF COMPUTED TOMOGRAPHY

For reasons of cost, speed, and availability, CT is still widely used for screening in the acute evaluation of stroke, head injury, or acute infections. It is especially useful for patients who are neurologically or medically unstable, uncooperative, or claustrophobic, as well as for patients with pacemakers or other metallic implants. If a mechanical ventilator is being used, CT is used for imaging because most respirators will not function in the high magnetic field of the MR scanner. Although some MR methods are sensitive to acute hemorrhage, its appearance is variable, and in daily clinical practice CT remains superior to MRI for detecting acute extravascular collections of blood, especially subarachnoid hemorrhage ([Fig. 13.1](#)). CT is also superior for evaluating cortical bone of the skull and spine, although MRI is superior in studying the bone marrow.

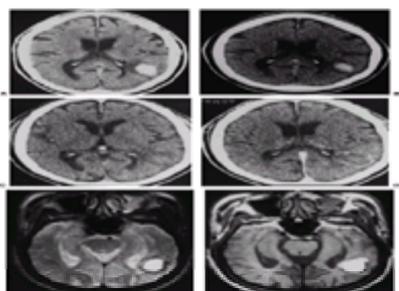

FIG. 13.1. Acute intracerebral hemorrhage with resorption over 6 weeks. **A:** Noncontrast axial CT in acute phase shows left parietal hyperdensity with mild mass effect and mild sulcal and ventricular effacement. **B:** Follow-up noncontrast axial CT 1 week later. Note the decrease in density of hemorrhage. Surrounding lucency is due to edema with persistent mass effect. Noncontrast **(C)** and contrast-enhanced **(D)** axial CT images 3 weeks posthemorrhage show further decrease in density of hemorrhage, which appears isodense in this phase with less surrounding lucency and mass effect. **D:** Peripheral ring enhancement postcontrast. T2-weighted **(E)** and T1-weighted **(F)** axial MR scans 6 weeks posthemorrhage demonstrate near-complete resolution of mass effect. In this subacute phase, hemorrhage typically appears hyperintense on both T2 and T1 pulse sequences, surrounded by a hypointense hemosiderin ring. (Courtesy of Dr. J.A. Bello and Dr. S.K. Hilal.)

Contrast-enhanced CT (CECT) is used to detect lesions that involve breakdown of the blood–brain barrier, such as brain or spinal tumors, infections, and other inflammatory conditions. CECT is often used to rule out cerebral metastases. However, it is less sensitive than Gd-enhanced MRI (Gd-MRI), which is also better for detection of other intracranial tumors and infections.

Intravenous CT contrast agents are based on iodine, and the older and cheaper agents are classified as high-osmolar contrast media (HOCM). Newer, nonionic agents, classified as low-osmolar contrast media (LOCM), are more expensive but less allergenic, and they cause less morbidity than do HOCM. LOCM are especially useful in patients at high risk for adverse reaction, such as those with severe heart disease, renal insufficiency, asthma, severe debilitation, or previous allergic reaction to iodinated contrast (HOCM).

Spiral or *helical* scanning increases scanning speed to less than 1 second per section and provides large-volume acquisitions that can be used for *three-dimensional* (3D) presentation of anatomic information. Single and multislice spiral scanning is now fast enough to allow acquisition of the entire neck or head during intravenous infusion of a bolus of contrast agent for reconstruction of CT angiography (CTA). Maximum intensity projection (MIP) reformations, often with 3D surface shading, display vascular features such as stenosis or aneurysm. Advantages of CTA over catheter angiography include more widely available technology, less specialized skill requirements, and less invasive intravenous administration of contrast material. However, the use of CTA has been growing slowly because of competition from existing MRA. In contrast to MRA, the iodinated contrast used is potentially more toxic because of allergic reactions and direct cardiac volume stress, as well as renal toxicity. Another limitation of CTA is the time-consuming processing required to edit out bone and calcium and to generate 3D surface renderings. Rapid CT is also used to generate brain perfusion studies during a bolus contrast injection. This method suffers from limited volume coverage and the risks of iodinated contrast injection, in contrast to MRI tissue perfusion methods.

USES OF MAGNETIC RESONANCE IMAGING

MRI is the neuroimaging method of choice for most intracranial and intraspinal abnormalities. The technical advantages of MRI are threefold: (1) Greater soft tissue contrast provides better definition of anatomic structures and greater sensitivity to pathologic lesions; (2) multiplanar capability displays dimensional information and relationships that are not readily available on CT; and (3) MRI can better demonstrate physiologic processes such as blood flow, CSF motion, and special properties of tissue such as water diffusion or biochemical makeup (using MRS). Other advantages include better visualization of the posterior fossa, lack of ionizing radiation, and better visualization of intraspinal contents.

There are some disadvantages of MRI. The most practical problem is the need for cooperation from the patient because most individual MRI sequences require several minutes and a complete study lasts 20 to 60 minutes. However, EPI and single-shot FSE methods can acquire low-resolution images in as little as 75 milliseconds and whole brain studies in 30 to 40 seconds. These can be used to salvage an adequate study for identifying or excluding major lesions in uncooperative patients. In addition, about 5% of all persons are claustrophobic inside the conventional MR unit. Oral or intravenous sedation can be used to ensure cooperation, but closer patient monitoring is then required. Development of low-magnetic-field, “open” MRI systems has improved patient acceptance, but these systems sacrifice image quality because of the lower signal-to-noise ratio. High-field (1.5 T), short-bore MR systems reduce patient perception of a closed tube while maintaining full MR capabilities.

MRI is absolutely contraindicated in patients with some metallic implants, especially cardiac pacemakers, cochlear implants, older-generation aneurysm clips, metallic foreign bodies in the eye, and implanted neurostimulators. Newer aneurysm clips have been designed to be nonferromagnetic and nontorqueable at high-magnetic-field strengths, but the U.S. Food and Drug Administration still urges caution in performing MRI in all patients with aneurysm clips. Individual clips may develop unpredictable magnetic properties during manufacture, and careful observation of initial images for magnetic artifacts should be used as an additional precaution. Published lists of MR-compatible clips and metallic objects provide advice about specific clip types and any unusual metallic implants.

Some authorities consider pregnancy (especially in the first trimester) a relative contraindication to MRI, primarily because safety data are incomplete. To date, no harmful effect of MRI has been demonstrated in pregnant women or fetuses, and late-pregnancy fetal MRI has been used clinically. An additional unknown risk to the fetus is the effect of intravenous MR contrast agents such as Gd- and iron-based agents. The urgency, need, and benefits of the MRI study for the patient should be considered in relation to potential unknown risks to the fetus in early pregnancy.

Indications for Gadolinium-enhanced MRI

Most intravenous contrast agents for MRI are chelates of gadolinium, a rare-earth heavy metal. The most commonly used agent is gadopentetate dimeglumine (Gd-DTPA), which is water-soluble and crosses the damaged blood–brain barrier in a manner similar to that of iodinated CT contrast media. The local accumulation of Gd-DTPA shortens both T1 and T2 relaxation times, an effect best seen on T1-weighted images. Lesions that accumulate extravascular Gd-DTPA appear as areas of high signal intensity on T1-weighted images. Comparison with precontrast images is needed to exclude preexisting high signal, such as hemorrhage, fat, and, occasionally, calcification. Specialized MR methods can improve detection of Gd-DTPA enhancement. For instance, magnetization transfer improves contrast enhancement, and fat suppression helps in the evaluation of the skull base and orbital regions. Unlike iodinated contrast material, Gd-DTPA administration is associated with few adverse reactions.

Gd-MRI has been most useful in increasing sensitivity to neoplastic and inflammatory lesions. This high sensitivity can show brain tumors that are often difficult to detect on CT, such as small brain metastases, schwannomas (especially within the internal auditory canal), optic nerve or hypothalamic gliomas, and meningeal carcinomatosis. In addition, the multiplanar capability of Gd-MRI delineates the extent of neoplastic lesions so well that the images can be used directly to plan neurosurgery and radiation therapy ([Fig. 13.2](#)).

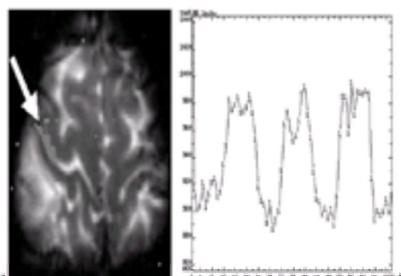

FIG. 13.2. Functional MRI for surgical planning. **A:** Axial T2*-weighted EPI image acquired during a left-hand grasping task shows activation of the precentral gyrus (*arrow*) immediately anterior to a region of high-signal cortical dysplasia scheduled for surgical resection. **B:** Time–intensity curves show three phases of increased signal, each during a 30-second period of repeated hand grasping separated by 30-second periods of rest. The rise in signal is produced by the BOLD effect, as local increases in blood flow in areas of cortical activation produce increased levels of oxyhemoglobin (decreased levels of deoxyhemoglobin) in capillaries and venules. (Y-axis represents signal intensity; X-axis shows sequential image numbers, each separated by 3 seconds. EPI GRE pulse sequence with TR 3000 ms, TE 90 ms, flip 90 degrees.)

Gd-MRI is superior to CECT in detecting cerebral metastases, but even Gd-MRI at standard dosages can miss metastatic lesions. Newer nonionic Gd-based contrast agents allow up to three times as much contrast agent to be used. In some cases, triple-dose Gd-MRI detects metastases not seen with the standard method. Similar high detection rates can be achieved with standard-dose Gd-DTPA when it is combined with magnetization-transfer MRI. Maximizing lesion sensitivity is especially significant in patients with solitary metastases, for whom surgical resection is a therapeutic option, in contrast to multiple lesions, for which radiation or chemotherapy may be better options.

MRI is the imaging method of choice for detecting the demyelinating plaques of multiple sclerosis in both the brain and spinal cord. Multiple sclerosis plaques are characteristically seen on T2-weighted images as multifocal hyperintense lesions within the periventricular white matter and corpus callosum. They appear ovoid and oriented along medullary veins, perpendicular to the long axis of the lateral ventricles (*Dawson fingers*). Gd-MRI can identify active inflammation by contrast enhancement of acute demyelinating plaques and distinguish them from nonenhancing chronic lesions. Serial Gd-MRI studies allow the progress of the disease to be monitored. Magnetization-transfer imaging, without Gd contrast injection, has also been used to identify abnormal white matter regions that appear normal on T2-weighted images.

Gd-MRI is vastly superior to CECT in the detection of meningitis, encephalitis (especially herpes simplex encephalitis and acute disseminated encephalomyelitis), and myelitis. Epidural abscess or empyema may also be better delineated on Gd-MRI. In acquired immunodeficiency syndrome, many kinds of lesions show increased signal intensity within the cerebral white matter on noncontrast T2-weighted images. These lesions can be further characterized by Gd-MRI. For example, if a single large or dominant enhancing mass is seen on Gd-MRI, the favored diagnosis is cerebral lymphoma. If multiple, small enhancing nodules are found, the possible diagnoses include cerebral toxoplasmosis, granulomas, or fungal infection. When no enhancement is present, the white matter lesions may be the result of human immunodeficiency virus encephalitis (if symmetric) or progressive multifocal leukoencephalopathy (if asymmetric). Thus, the presence or absence of contrast enhancement, the character of contrast enhancement, and the pattern of signal abnormality are all important features in the differential diagnosis.

Gd-MRI is also useful in evaluation of the spine. Herniated discs and degenerative spondylosis can be well evaluated on noncontrast MRI in the unoperated patient, but Gd-MRI is needed in patients with a “failed back syndrome” to separate nonenhancing recurrent disc herniation from enhancing postsurgical scarring or fibrosis. Identification and delineation of spinal tumors and infections are also improved with Gd-MRI. However, Gd enhancement of vertebral bone marrow metastases may make them isointense with normal fatty marrow. Screening precontrast T1-weighted images of the spine should always be obtained. MRI is much more sensitive to bone marrow metastases than conventional radionuclide bone scans. The emergency evaluation of spinal cord compression is also best done with pre- and postcontrast Gd-MRI because multilevel disease can be directly visualized and definitive characterization of lesions can be done immediately (i.e., intra- versus extramedullary, dural and spinal involvement). For these reasons, the indications for conventional and CT-myelography are decreasing. Outside the spine, fat-suppressed MRI of spinal nerve roots and peripheral nerves, known as MR *neurography*, identifies compressive or traumatic nerve injuries.

Appropriate Utilization of Gadolinium-Enhanced MRI

Some experts have proposed universal administration of Gd for MRI. The use of Gd, however, adds to the direct costs of MRI and increases imaging time, as well as patient discomfort from the intravenous injection. Others recommend that Gd-MRI should be restricted to specific clinical situations in which efficacy has been demonstrated (except when a significant abnormality on routine noncontrast MRI requires further characterization).

In some clinical situations, Gd-MRI is not very useful because relatively few contrast-enhancing lesions are typically found. These clinical situations include complex partial seizures, headache, dementia, head trauma, psychosis, low back or neck pain (in unoperated patients), and congenital craniospinal anomalies. MRI evaluation in many of these conditions would be improved by special MR pulse sequences directed to the structures of greatest interest. For example, patients with temporal lobe epilepsy or Alzheimer disease benefit most by high-resolution imaging of the temporal lobes for evidence of hippocampal atrophy or sclerosis ([Fig. 13.3](#)). Patients who have experienced remote head trauma or child abuse might be best served by a T2-weighted GRE pulse sequence, which is more sensitive than the SE pulse sequence in detecting lesions associated with hemosiderin deposition, such as axonal shear injuries or subarachnoid hemosiderosis from repeated subarachnoid hemorrhages.

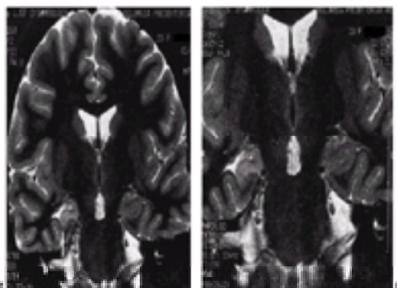

FIG. 13.3. High-resolution image of the temporal lobes. **A:** High-resolution (512 × 512 matrix) coronal MR scan through the temporal lobes obtained with the use of short-tau inversion recovery (STIR) pulse sequence shows increased signal intensity within the right hippocampus (arrow). The normal left hippocampus is well visualized, with clear definition of internal architecture. **B:** Magnification view allows close inspection of the hippocampi with no significant distortion because a high-resolution image was obtained. Patient has presumed right mesial temporal sclerosis associated with a clinical and electroencephalogram-defined syndrome of right temporal lobe epilepsy.

Magnetic Resonance Angiography

On standard SE images, the major arteries and veins of the neck and brain are usually seen as areas of signal void because of relatively fast blood flow. A GRE pulse sequence can show flowing blood as areas of increased signal intensity known as *flow-related enhancement* (not to be confused with Gd contrast enhancement). In these images, the soft tissues appear relatively dark. After a series of contiguous thin sections is obtained with either two-dimensional or 3D GRE techniques, a map of the blood vessels is reconstructed as a set of MIP angiograms that can be viewed in any orientation and displayed with 3D surface shading. These MRA images, like a conventional angiogram, can show the vascular anatomy but also have the advantage of multiple viewing angles that provide oblique and other nonstandard angiographic views. An advantage of MRA over CTA is that it is completely noninvasive, requiring no contrast injection. MRA does not require specialized catheter skills and avoids the 0.5% to 3% risk of neurologic complications associated with arterial catheter angiography.

In the evaluation of the carotid arteries in the neck or the arteries of the circle of Willis, the most commonly used MRA technique is the *time-of-flight* (TOF) method. TOF is sensitive to T1 relaxation effects and may produce false-positive or obscuring high-signal artifacts from orbital fat, hemorrhage, or areas of Gd enhancement. Another important MRA technique, the *phase-contrast* (PC) technique, depends on the phase (rather than magnitude) of the MR signal. PC technique shows the direction and velocity of blood flow, may be adjusted to low or high flow sensitivity, and is useful for evaluating altered hemodynamics, such as flow reversal after major vessel occlusion or stenosis.

MRA occasionally overestimates cervical carotid stenosis because of local turbulent flow, but it compares favorably with conventional angiography in detecting carotid stenosis. Conventional angiography is still the “gold standard” for cerebrovascular imaging, but extracranial carotid evaluation is now done primarily with ultrasound and MRA.

Indications for MRA include stroke, transient ischemic attack (TIA), possible venous sinus thrombosis, arteriovenous malformation (AVM), and vascular tumors (for delineation of vascular supply and displacements). It is thought that MRA reliably detects aneurysms as small as 3 mm. Conventional angiography, however, is still the most sensitive examination for evaluation of intracranial aneurysms or AVMs because of its higher spatial resolution and ability to observe the rapid sequence of

vascular filling, especially the early venous filling seem with AVMs.

Functional MRI

The term *functional* is used here in a broad sense to encompass several MRI methods that are used to image physiologic processes such as tissue blood flow, water diffusion, and biochemical makeup (with MRS), as well as cerebral activation with sensory, motor, and cognitive tasks. Tissue blood flow is most commonly imaged with MRI using a *first-pass* or *bolus-tracking* method that records the signal changes occurring when rapidly repeated images are acquired during the first passage of an intravascular bolus of paramagnetic contrast material through the brain, usually Gd-DTPA. Using T2*- or T2-weighted EPI or fast GRE techniques, MR images are acquired every 1 to 3 seconds over the whole brain, and the signal decreases that occur in each tissue with passage of the contrast bolus are plotted against time. The area under this time-intensity curve is proportional to cerebral blood volume (CBV), and other manipulations of the data can give cerebral blood flow (CBF), mean transit time (MTT), and other measures of tissue perfusion. This method has been used most extensively with primary brain tumors, where CBV seems to correlate well with histologic tumor grade and demonstrates responses to treatment of the tumor. The obvious application to cerebral ischemic disease has become more widespread, and measures of perfusion delay, such as MTT and time to peak, are sensitive indicators of small reductions in cerebral perfusion. A second method of MR perfusion imaging is called *spin tagging* or *TOF* imaging and, like TOF MRA, depends on T1 relaxation and flow enhancement phenomena, without the use of injected contrast agents. This method is less widely used than bolus tracking but gives more quantitative CBF measurements.

A second important functional MRI technique is *diffusion-weighted imaging* (DWI). This is most commonly performed using an EPI SE pulse sequence with gradients added before and after the 180-degree pulse. On DW images, areas of high diffusion show up as low signal, and those with low diffusion appear as high signal. Quantitative *apparent diffusion coefficient* (ADC) maps can be generated to display diffusion with the opposite polarity: high ADC as high signal and low ADC as low signal. Severe cerebral ischemia causes a rapid decrease in intracellular diffusion, and high signal appears on DWI within minutes of cell injury. After the initial reduction in diffusion, there is a gradual rise through normal to prolonged diffusion rates during the 1 to 2 weeks after infarction, as cells disintegrate and freely diffusible water dominates the encephalomalacic tissue. A minor pitfall of DWI is called "T2 shine-through," where high signal on T2-weighted images may produce high signal on DWI, falsely indicating reduced diffusion. This error can be avoided by the use of calculated ADC maps. DWI is an essential part of acute stroke imaging, and because it takes less than 1 minute to acquire a whole-brain study, it is widely used. DWI can be combined with perfusion imaging to identify the so-called *penumbra zone* of potentially salvageable tissue within the area of reduced perfusion but outside the unrecoverable infarct, represented by DWI high signal.

MRS can be performed with clinical high-field MR scanners. Proton spectroscopy is most widely used and produces semiquantitative spectra of common tissue metabolites, including *N*-acetylaspartate (NAA; a marker of healthy neurons and axons), creatine (the molecular storage depot for high-energy phosphates), choline (a component of cell membranes and myelin), and lactate (elevated with normal tissue energetic stress and in many pathologic tissues). Proton spectra can be obtained from as little as 0.5 cc of tissue at 1.5 T and MRS images can be generated to show metabolite distributions, albeit at lower spatial resolution than anatomic MR images. The most widely accepted clinical use of proton MRS is the identification of brain neoplasms that tend to show a characteristic but not completely specific pattern of elevated choline, reduced NAA, and elevated lactate. MRS is also used to characterize multiple sclerosis plaques, degenerative diseases such as Alzheimer disease or amyotrophic lateral sclerosis, and metabolic disorders such as MELAS.

Using MRI to map cerebral activation is specifically called *functional MRI* (fMRI). The technique most widely used is the *blood-oxygen-level-dependent* (BOLD) method, which is based on local increases in CBF and the consequent shift from deoxyhemoglobin to oxyhemoglobin in areas of cerebral activation. With T2*- or T2-weighted EPI or fast GRE images and rapidly repeated acquisitions (every 1 to 3 seconds), MR images show small increases in signal in areas of cerebral activation. BOLD fMRI has been used in research on motor, sensory, and cognitive activation. Growing clinical applications of fMRI include mapping of motor, sensory, and language function prior to surgery, radiation therapy, or embolization procedures; monitoring recovery of function after brain injury or stroke; and mapping specific cognitive changes in degenerative brain diseases.

PARADIGM: DIAGNOSTIC WORKUP FOR STROKE

In the first evaluation of patients with stroke, either CT or MRI can be used. In many centers, CT is the primary choice because of availability, immediate access, less need for patient cooperation, and lower cost. In addition, hemorrhage, calcification, and skull fracture are easy to recognize on CT. CT is less sensitive than MRI, however, in showing nonhemorrhagic infarction in the first 24 hours after the ictus. In addition, infarcts within the brainstem and cerebellum are usually better demonstrated by MRI.

MRI is the modality of choice for acute ischemic stroke because of the high sensitivity and specificity of DWI. As noted above, DWI can specifically identify cerebral infarction within minutes of onset, and, when combined with quantitative ADC maps, can specify the age of a lesion to within a few days. FLAIR imaging also shows high signal in acute infarcts and is sensitive to lesions within the first 6 to 12 hours. A comparison of T2-weighted and proton-density MRI to CT found that within the first 24 hours 82% of lesions were seen on MRI, whereas only 58% were seen on CT. The earliest changes are seen on proton-density-weighted images, with hyperintensity present within the affected cortical gray matter. During the first 5 days after stroke onset, Gd enhancement may be seen within the small arteries of the ischemic vascular territory, with gyral cortical enhancement present 5 days to several months after onset. The focal reversible lesions of TIAs are also more frequently seen on MRI than on CT.

MRA and duplex ultrasonography of the carotid arteries are then used to evaluate possible underlying carotid stenosis. If necessary, invasive angiography can corroborate the presence of carotid stenosis and may depict ulcerations that are not well seen on MRA or duplex ultrasonography.

MRA of the brain is also useful in determining patency of the vessels of the circle of Willis. Acute occlusions of the major vessels of the circle of Willis or of the superior portions of the internal carotid arteries and basilar artery can be detected, but occlusion of small distal branches is not as well demonstrated ([Fig. 13.4](#)). Arterial and venous flow can be separated to identify venous occlusion. MRA can also be used serially for evaluation of therapy, such as intraarterial thrombolysis, but conventional angiography may still be useful in early diagnostic evaluation and is necessary for intraarterial thrombolytic therapy.

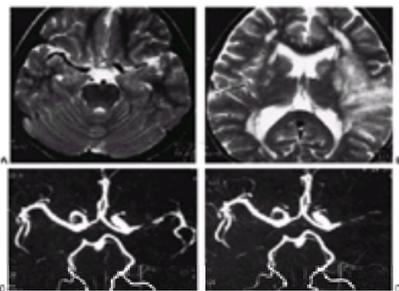

FIG. 13.4. A,B: T2-weighted axial MR scans demonstrate increased signal intensity within the opercular areas of the left frontal and temporal lobes, consistent with acute ischemia or infarction. Note the decreased visualization of left middle cerebral artery flow void as compared to right. **C:** Collapsed (base) view of an MR angiogram of the circle of Willis shows marked stenosis of the M1 (first) segment of the left middle cerebral artery (MCA). **D:** Follow-up collapsed (base) view of an MR angiogram of the circle of Willis demonstrates virtually complete occlusion of the left MCA. Progression occurred despite aggressive medical therapy, including anticoagulation.

CHAPTER 14. ELECTROENCEPHALOGRAPHY AND EVOKED POTENTIALS

RONALD G. EMERSON, THADDEUS S. WALCZAK AND TIMOTHY A. PEDLEY

[Electroencephalography](#)
[Clinical Utility of Electroencephalography](#)
[Evoked Potentials](#)
[Digital Eeg Technology and Computerized Eeg](#)
[Suggested Readings](#)

Electroencephalography (EEG) and evoked potentials (EPs) are measures of brain electric activity. EEG reflects spontaneous brain activity, whereas EPs reflect activity of the central nervous system in response to specific stimuli. In contrast to anatomic imaging techniques, such as computed tomography and magnetic resonance imaging, which provide information about brain structure, EEG and EP studies provide information about brain function. Functional and structural investigations are often complementary. Electrophysiologic studies are particularly important when neurologic disorders are unaccompanied by detectable alteration in brain structure. This chapter provides an overview of the current capabilities and limitations of these techniques in clinical practice.

ELECTROENCEPHALOGRAPHY

Normal Adult EEG

EEG activity is characterized by the frequency and voltage of the signals. A major feature of the EEG during wakefulness is the alpha rhythm, an 8- to 12-cycles-per-second (cps) parietooccipital rhythm ([Fig. 14.1](#)). The alpha rhythm is best seen when the patient is awake and relaxed with eyes closed. It attenuates when the eyes are opened, or the subject is alerted. Beta activity, between 13 and 25 cps, is usually maximal in the frontal and central regions. High-voltage beta activity suggests the effect of sedative-hypnotic medication. A small amount of slower frequencies may be diffusely distributed.

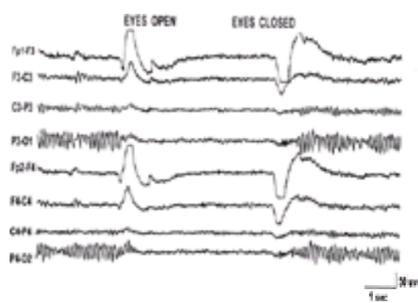

FIG. 14.1. Normal EEG in an awake 28-year-old man.

Sleep is divided into five stages on the basis of the combinations of EEG patterns, eye movements, and axial electromyography (EMG). Stage 1 is a transitional period between wakefulness and sleep. The alpha rhythm disappears during stage 1 and is replaced by low-voltage, slower activity. Vertex waves, high-voltage, "sharp" transients, are recorded maximally at the vertex. Stage 2 sleep is characterized by sleep spindles (symmetric 12- to 14-cps sinusoidal waves). The EEG in stages 3 and 4 is composed of high-voltage, widely distributed, slow-wave activity. Rapid eye movement (REM) sleep is characterized by low-voltage, mixed-frequency activity, similar to that in early stage 1, together with REM and generalized atonia. REM occurs about 90 minutes after sleep onset in adults and is not usually seen in routine studies. The presence of REM in a daytime EEG suggests sleep deprivation, withdrawal from REM-suppressant drugs, alcohol withdrawal, or narcolepsy ([Chapter 145](#)).

Common EEG Abnormalities

Diffuse slowing of background rhythms is the most common EEG abnormality ([Fig. 14.2](#)). This finding is nonspecific and is present in patients with diffuse encephalopathies of diverse causes, including toxic, metabolic, anoxic, and degenerative. Multiple structural abnormalities can also cause diffuse slowing.

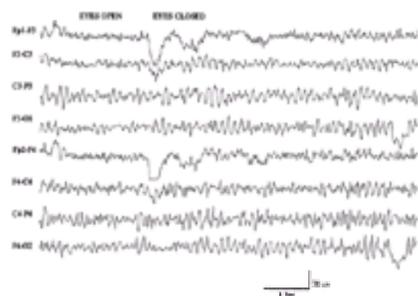

FIG. 14.2. Diffuse slowing in a 67-year-old patient with dementia. Six- to seven-cps activity predominates over the parietooccipital regions. Although reactive to eye closure, the frequency of this rhythm is abnormally slow.

Focal slowing suggests localized parenchymal dysfunction ([Fig. 14.3](#)). Focal neuroradiologic abnormalities are found in 70% of patients with significant focal slowing and must always be suspected in this situation. Focal slowing may also be seen in patients with focal seizure disorders, even when no lesions are found. Focal voltage attenuation usually indicates localized lesions of gray matter but may also be seen with focal subdural, epidural, or even subgaleal fluid collections ([Fig. 14.3](#)).

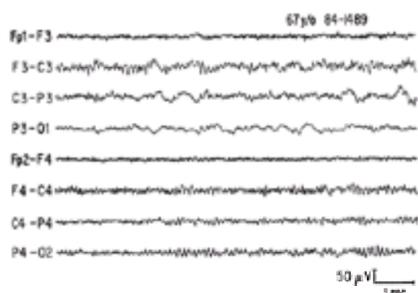

FIG. 14.3. Focal slow activity with attenuation of the alpha rhythm over the left hemisphere in a 67-year-old patient with an acute left hemispherical infarction.

Triphasic waves typically consist of generalized synchronous waves occurring in brief runs (Fig. 14.4). Approximately one-half the patients with triphasic waves have hepatic encephalopathy, and the remainder have other toxic-metabolic encephalopathies.

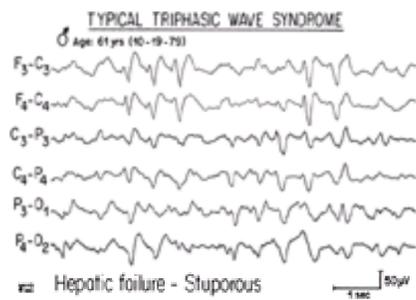

FIG. 14.4. Triphasic waves in a 61-year-old patient with hepatic failure. (Courtesy of Bruce J. Fisch.)

Epileptiform discharges (EDs) are the interictal hallmark of epilepsy. They are strongly associated with seizure disorders and are uncommon in normal adults. The type of ED may also suggest a specific epileptic syndrome (see the following).

Periodic lateralizing epileptiform discharges (PLEDs) suggest the presence of an acute destructive cerebral lesion. Focal EDs recur at 1 to 2 cps in the setting of a focally slow or attenuated background (Fig. 14.5). In a study of nearly 600 patients with PLEDs, the finding was related to an acute cerebral infarction in 35%, to other mass lesions in 26%, and to cerebral infection, anoxia, or other causes in the remainder. Clinically, PLEDs are associated with seizures, obtundation, and focal neurologic signs.

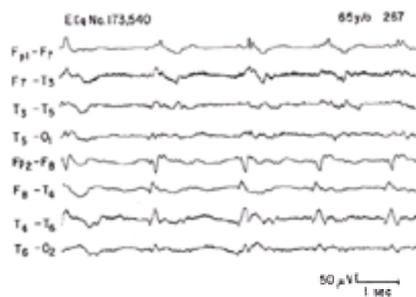

FIG. 14.5. Right hemispherical PLEDs in a 65-year-old patient with herpes simplex encephalitis. (From Pedley TA, Emerson RG. Clinical neurophysiology. In: Bradley WG, Daroff RB, Fenichel GM, Marsden CD, eds. *Neurology in clinical practice*, 2nd ed. Boston: Butterworth-Heinemann, 1996:460; with permission.)

Generalized periodic sharp waves typically recur at 0.5 to 1 cps on an attenuated background. This pattern is most commonly seen following cerebral anoxia. It is also recorded in about 90% of patients with Creutzfeldt-Jakob disease.

CLINICAL UTILITY OF ELECTROENCEPHALOGRAPHY

Epilepsy

The EEG is the most useful laboratory test to help establish the diagnosis of epilepsy and assist in the accurate classification of specific epileptic syndromes. Characteristic interictal EDs strongly support the diagnosis of epilepsy, but absence of EDs does not rule out this diagnosis. EDs are recorded in 30% to 50% of epileptic patients on the first routine EEG and in 60% to 90% by the third routine EEG. Further EEGs do not appreciably increase the yield. Thus, 10% to 40% of patients with epilepsy do not demonstrate interictal discharges, even on several EEGs. Sleep, sleep deprivation, hyperventilation, and photic stimulation increase the likelihood of recording EDs in some patients.

Conversely, interictal EDs are infrequent in healthy normal subjects or patients without epilepsy. EDs occur in only 1.5% to 3.5% of healthy normal children. Siblings of children with benign focal epilepsy or petit mal absence without seizures may also have interictal EDs recorded incidentally. EDs occur in 2.7% of adult patients with various illnesses, including neurologic diseases, but with no history of seizures. The presence of EDs with the appropriate clinical findings strongly supports the diagnosis of epilepsy but does not establish it unequivocally.

The type of interictal ED, together with the patient's clinical features, often allows diagnosis of a specific epileptic syndrome. Confident diagnosis of an epileptic syndrome leads to proper treatment and provides information regarding prognosis. Table 14.1 summarizes specific characteristics of epileptiform abnormalities in some common epileptic syndromes. Clinical features of the syndromes are summarized in Chapter 140). A useful example is the distinction between generalized 3-cps spike and wave and temporal spike and wave. Three-cps spike and wave is seen in childhood absence epilepsy, an epileptic syndrome with early age of onset, absence and tonic-clonic seizures, and relatively good prognosis (Fig. 14.6). Either ethosuximide (Zarontin) or valproic acid (Depakene) is the medication of choice. In contrast, temporal-lobe spikes are seen in complex partial seizures or complex partial seizures with secondary generalization (Fig. 14.7). Prognosis is poorer, and phenytoin sodium (Dilantin), carbamazepine (Tegretol), or barbiturates are the medications of choice.

West syndrome (Infantile spasms)	No organized background rhythm Random high-voltage slow activity Multifocal epileptiform discharges Abrupt attenuation (infantile spasms)
Lennox-Gastaut syndrome	Slow generalized spike and wave (\approx 2 cps) Significantly slowed background rhythm
Childhood absence epilepsy	Generalized spike and wave (\approx 3 cps) Usually precipitated by hyperventilation Normal background rhythm
Benign rolandic epilepsy	Focal centrotemporal epileptiform discharge Normal background rhythm
Juvenile myoclonic epilepsy	Generalized polyspike wave (often \approx 3 cps) May be precipitated by photic stimulation Normal background rhythm
Localization-related epilepsy (e.g., temporal lobe seizures)	Focal epileptiform discharges Occasional focal slowing Occasional mild slowing of background

TABLE 14.1. EPILEPTIFORM ABNORMALITIES IN THE COMMON EPILEPSY SYNDROMES

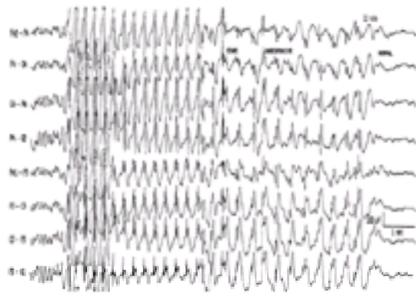

FIG. 14.6. Ten-second absence seizure in an 11-year-old with staring spells. Three- to four-cps generalized spike wave is seen at the beginning of the seizure. The rate gradually slows toward the end of the seizure. Then patient was asked to follow a simple command 6 seconds after seizure onset and was unable to do so.

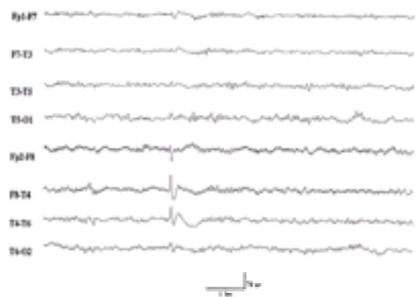

FIG. 14.7. Right anterior temporal epileptiform discharge in a 32-year-old patient with complex partial seizures emerging from the right temporal lobe.

Dementia and Diffuse Encephalopathies

The EEG provides useful clues in obtunded patients. Triphasic waves suggest a toxic-metabolic cause. High-voltage beta activity suggests the presence of sedative-hypnotic medications. Generalized voltage attenuation is seen in Huntington disease. Generalized periodic sharp waves are seen in about 90% of patients with Creutzfeldt-Jakob disease within 12 weeks of clinical onset. EEG is critical when spike-wave stupor is the cause of obtundation. EEG may be normal early in the course of Alzheimer disease, when cognitive changes are minor and the diagnosis is still uncertain. As moderate to severe symptoms appear, diffuse slowing is seen (see [Fig. 14.2](#)). Almost all patients with biopsy-proven Alzheimer disease have unequivocal EEG abnormalities within 3 years of the onset of symptoms. Focal slowing is uncommon and, if present, suggests multiinfarct dementia or another multifocal cause.

Focal Brain Lesions

As neuroimaging has become widely available, EEG has come to play a less important role in the diagnosis of structural lesions. EEG is necessary, however, to assess the epileptogenic potential of mass lesions. Focal EEG abnormalities accompany one-half of hemispherical transient ischemic attacks. Normal EEG in a patient with a neurologic deficit strongly suggests a lacunar infarction. EEG slowing in hemispherical infarcts gradually improves with time, whereas focal slowing in neoplasms remains the same or worsens. This difference can be useful when neuroradiologic findings do not distinguish between semiacute infarction and neoplasm.

Cerebral Infections

Focal changes are noted in more than 80% of patients with herpes encephalitis, and PLEDs are seen in more than 70% (see [Fig. 14.5](#)). PLEDs typically appear 2 to 15 days after onset of illness, but the interval may be as long as 1 month. Serial EEG is therefore useful if early studies are nonfocal. Early focal findings strongly suggest this diagnosis if the clinical picture is compatible, and may indicate the appropriate site for biopsy. Virtually diagnostic EEG changes are seen in subacute sclerosing panencephalitis: stereotyped bursts of high-voltage delta waves at regular intervals of 4 to 10 seconds. Early in the disease, slow-wave bursts may be infrequent or confined to sleep, so serial EEG may be useful. EEG findings in patients infected with human immunodeficiency virus are nonspecific. Diffuse slowing may precede clinical neurologic manifestations. The slowing becomes more persistent in patients with dementia related to acquired immunodeficiency syndrome. Focal slowing suggests the presence of a superimposed cerebral lesion, such as lymphoma or toxoplasmosis.

EVOKED POTENTIALS

Principles of Evoked Potential Recording

Visual, auditory, and somatosensory stimuli cause small electric signals to be produced by neural structures along the corresponding sensory pathways. These EPs are generally of much lower voltage than ongoing spontaneous cortical electric activity. They are usually not apparent in ordinary EEG recordings and are detected with the use of averaging techniques. Changes in EPs produced by disease states generally consist of delayed responses, reflecting conduction delays in responsible pathways, or attenuation or loss of component waveforms, resulting from conduction block or dysfunction of the responsible generator.

Clinically, EP tests are best viewed as an extension of the neurologic examination. Abnormalities identify dysfunction in specific sensory pathways and suggest the location of a responsible lesion. They are most useful when they identify abnormalities that are clinically inapparent or confirm abnormalities that correspond to vague or equivocal signs or symptoms.

Visual Evoked Potentials

The preferred stimulus for visual evoked potential (VEP) testing is a checkerboard pattern of black and white squares. *Pattern reversal* (i.e., change of the white squares to black and the black squares to white) produces an occipital positive signal, the P100, approximately 100 milliseconds after the stimulus. Because fibers arising from the nasal portion of each retina decussate at the optic chiasm ([Fig. 14.8](#)), an abnormality in the P100 response to stimulation of one eye necessarily implies dysfunction anterior to the optic chiasm on that side. Conversely, delayed P100 responses following stimulation of both eyes separately may result from bilateral abnormalities either anterior or posterior to the chiasm or at the chiasm. Unilateral hemispherical lesions do not alter the latency of the P100 component because of the contribution of a normal response from the intact hemisphere.

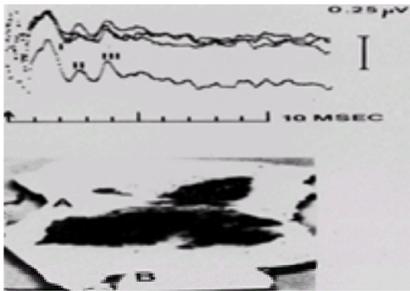

FIG. 14.11. Abnormal BAEP recorded in a patient with a brainstem hemorrhage sparing the lower one-third of the pons. Waves IV and V are lost, but waves I, II, and III are preserved. (From Chiappa KH. Evoked potentials in clinical medicine. In: Baker AB, Baker LH, eds. *Clinical neurology*. New York: Harper & Row, 1990:22; with permission.)

BAEPs are sensitive for detection of tumors of the eighth cranial nerve; abnormalities are demonstrated in more than 90% of patients with acoustic neuroma. BAEP abnormalities seen with acoustic neuromas and other cerebellopontine angle tumors range from prolongation of the I to III interpeak interval, thereby indicating a conduction delay between the distal eighth cranial nerve and lower pons (see Fig. 14.10), to preservation of wave I with loss of subsequent components, to loss of all BAEP waveforms. The sensitivity of the BAEP to acoustic nerve lesions can be extended by decreasing the stimulus intensity over a prescribed range and evaluating the effects on the BAEP waveforms (*latency-intensity function*). Some patients with small intracanalicular tumors have normal standard BAEPs, and abnormality is revealed only by latency-intensity function testing.

BAEPs help establish the diagnosis of multiple sclerosis when they detect clinically unsuspected or equivocal brainstem lesions. BAEPs are abnormal in about 33% of patients with multiple sclerosis, including 20% of those who have no other signs or symptoms of brainstem lesions. The BAEP findings in multiple sclerosis consist of the absence or decreased amplitude of BAEP components, or an increase in the III to V interpeak latency.

BAEPs may be useful in demonstrating brainstem involvement in generalized diseases of myelin, such as metachromatic leukodystrophy, adrenoleukodystrophy, and Pelizaeus-Merzbacher disease. BAEP abnormalities may also be demonstrable in asymptomatic heterozygotes for adrenoleukodystrophy.

BAEPs are also used to evaluate hearing in infants and others who cannot cooperate for standard audiologic tests. The latency-intensity test permits determination of the wave V threshold, as well as the relationship of wave V latency to stimulus intensity, and often allows characterization of hearing loss as sensorineural or conductive.

Somatosensory Evoked Potentials

Somatosensory evoked potentials (SSEPs) are generally elicited by electric stimulation of the median and posterior tibial nerves, and reflect sequential activation of structures along the afferent sensory pathways, principally the dorsal column-lemniscal system. The components of median nerve SSEP testing important to clinical interpretation include the Erb point potential, recorded as the afferent volley traverses the brachial plexus; the N13, representing postsynaptic activity in the central gray matter of the cervical cord; the P14, arising in the lower brainstem, most likely in the caudal medial lemniscus; the N18, attributed to postsynaptic potentials generated in the rostral brainstem; and the N20, corresponding to activation of the primary cortical somatosensory receiving area (Fig. 14.12). The posterior tibial SSEP is analogous to the median SSEP and includes components generated in the gray matter of the lumbar spinal cord, brainstem, and primary somatosensory cortex.

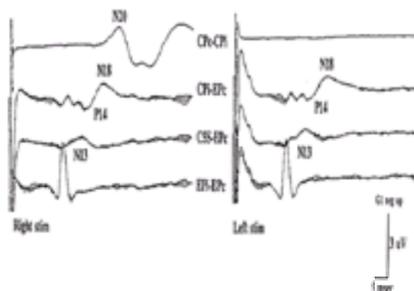

FIG. 14.12. Median SEPs in a patient with a right putamen hemorrhage. Following right median nerve stimulation, the SEP is normal. Following left median nerve stimulation, the N20 cortical response is absent, while more caudally generated potentials are preserved.

SSEPs are altered by diverse conditions that affect the somatosensory pathways, including focal lesions (strokes, tumors, cervical spondylosis, syringomyelia) or diffuse diseases (hereditary system degenerations, subacute combined degeneration, and vitamin E deficiency). Of patients with multiple sclerosis, 50% to 60% have SSEP abnormalities, even in the absence of clinical signs or symptoms. SSEP abnormalities are also produced by other diseases affecting myelin (adrenoleukodystrophy, adrenomyeloneuropathy, metachromatic leukodystrophy, Pelizaeus-Merzbacher disease). In adrenoleukodystrophy and adrenomyeloneuropathy, SSEP abnormalities may be present in asymptomatic heterozygotes. Abnormally large-amplitude SSEPs, reflecting enhanced cortical excitability, are seen in progressive myoclonus epilepsy, in some patients with photosensitive epilepsy, and in late-infantile ceroid lipofuscinosis.

SSEPs are commonly used to monitor the integrity of the spinal cord during neurosurgical, orthopedic, and vascular procedures that generate risk of injury; SSEPs can detect adverse changes before they become irreversible. Although SSEPs primarily reflect the function of the dorsal columns, they are generally sensitive to spinal cord damage produced by compression, mechanical distraction, or ischemia.

Motor Evoked Potentials

It is possible to assess the descending motor pathways by motor evoked potential (MEP) testing. MEP studies entail stimulation of the motor cortex and recording the compound muscle action potential of appropriate target muscles. The cortex is stimulated either by direct passage of a brief high-voltage electric pulse through the scalp or by use of a time-varying magnetic field to induce an electric current within the brain. Although the clinical utility of this technique is not defined, MEPs evaluate the integrity of the descending motor pathways, complementing data about sensory pathways provided by SSEPs. MEPs also provide information about diseases of the motor system.

DIGITAL EEG TECHNOLOGY AND COMPUTERIZED EEG

Traditional EEG machines record EEG signals as waveforms on paper with pens driven by analog amplifiers. These devices are gradually being replaced by computerized systems that convert EEG data to a digital format, store the transformations on digital media, and display them on computer screens. These systems facilitate interpretation by allowing the physician to manipulate EEG data at the time of interpretation and to supplement standard methods of EEG analysis with display and signal-processing techniques that emphasize particular findings to optimal advantage.

Digital EEG technology has not fundamentally altered the manner in which EEG is interpreted. Rather, it allows standard interpretative strategies to be used more

effectively. In conventional paper-based EEG, a technologist sets all recording parameters, including amplification, filter settings, and montages, at the time EEG is performed. In contrast, digital EEG systems permit these settings to be altered off-line when the EEG is interpreted. The EEG technician can select the best settings for viewing a particular waveform or pattern of interest, or examine it at different instrument settings.

Digital technology has also made it possible to implement computerized pattern-recognition techniques to identify clinically significant electric activities during continuous recordings. For example, automated spike- and seizure-detection algorithms are routinely used in epilepsy monitoring units during video-EEG recording. Currently available software results in a high rate of false-positive detections, and careful manual review of computer-detected events is mandatory. Similar techniques may be useful in intensive care units.

Digital systems also permit use of signal-processing and computer-graphic techniques to reveal features of the EEG that may not be apparent from visual inspection of "raw" waveforms. For example, computer averaging improves the signal-to-noise ratio of interictal spikes, revealing details of the electric-field distributions and timing relationships that cannot be discerned from the routine EEG (Fig. 14.13). The fast Fourier transform (FFT) can quantify frequencies in EEG background activity, and computer-graphic techniques display these data in an appealing and easily understood manner (Fig. 14.14). Dipole source localization has been applied to both interictal spikes and ictal discharges in patients with epilepsy. While these and other forms of processed EEG are at present best used to supplement conventional visual analysis, many computerized techniques are based on specific critical assumptions that, if misapplied, may lead to erroneous conclusions. Therefore, at present, findings from computer-processed EEG should be used clinically with caution and generally only when standard visual analysis is supportive and consistent.

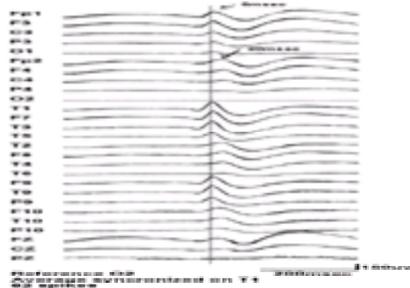

FIG. 14.13. Averaged left temporal spike in a patient with complex partial seizures associated with mesial temporal sclerosis. Note the time-locked signal over the right frontal-temporal regions occurring after a 20 millisecond delay. This most likely reflects propagation of the spike discharge from the left temporal lobe along neural pathways to the right side. Such time delays cannot be appreciated in routine EEG recordings.

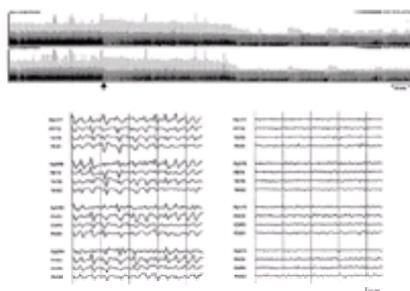

FIG. 14.14. Compressed spectral array (CSA) depicting the voltage spectra derived from two channels of EEG in a patient in nonconvulsive status epilepticus. The abscissa of each chart represents time as indicated, and the ordinate represents frequency from 0 to 30 Hz. Voltage is encoded with use of a gray scale, as illustrated. There is an abrupt change in the CSA, corresponding to a decrease in the voltage of low-frequency ictal activity when diazepam is administered intravenously (arrow). The accompanying EEG samples correspond to representative epochs before (**left**) and after (**right**) treatment.

CHAPTER 15. ELECTROMYOGRAPHY AND NERVE CONDUCTION STUDIES IN NEUROMUSCULAR DISEASE

DALE J. LANGE AND WERNER TROJABORG

[Electromyography](#)
[Neuromuscular Transmission Disorders](#)
[Suggested Readings](#)

Needle electromyography (EMG) and nerve conduction studies are extensions of the neurologic examination. The primary role for electrophysiologic studies is to separate neurogenic from myogenic disorders. For example, the characteristic EMG findings of stiff-man syndrome (Moersch-Woltman syndrome) and Issac syndrome are the basis for these diagnoses. Repetitive stimulation abnormalities define the Lambert-Eaton syndrome. Characteristic abnormalities in nerve conduction define some entrapment neuropathies or multifocal motor neuropathy with conduction block. EMG and nerve conduction findings may provide important information to confirm a diagnosis, such as myasthenia gravis, Guillain-Barré syndrome, or polymyositis. Even normal EMG and nerve conduction findings may provide essential information for diagnosis. For example, normal sensory studies in an anesthetic limb after trauma suggest nerve root avulsion. Normal repetitive stimulation studies in the presence of severe weakness is strong evidence against myasthenia gravis.

However, EMG and nerve conduction studies are subject to many technical errors that can affect interpretation. For example, low limb temperature can lead to a false diagnosis of neuropathy or may fail to reveal excessive decrement during repetitive nerve stimulation in patients with myasthenia gravis. These and other technical considerations and normal variants, discussed in monographs listed in the references, are essential for performing and interpreting these tests.

Nerve conduction studies are performed on motor and sensory nerves, usually in the distal portions of limbs (hand and feet). Conduction, however, can also be measured to biceps, deltoid, quadriceps, and muscles of the trunk (diaphragm and rectus abdominis). High-voltage electrical and magnetic stimulators activate spinal roots and descending pathways from the brain and spinal cord.

Similar techniques are used for motor and sensory nerve conduction studies ([Fig. 15.1](#)). An electrical stimulus is applied to the skin directly over a nerve. One electrical response is recorded from the innervated muscle (motor) or a more proximal portion of the nerve (sensory). The stimulus intensity is increased until the response no longer grows in amplitude (supramaximal response). The interval between the onset of the stimulus and the onset of the evoked response is the latency. Because nerve fibers vary in diameter and speed of conduction, a supramaximal stimulus ensures that all nerve fibers are activated, facilitating comparison of latencies in different people or in serial studies of the same person. The calculated conduction velocity corresponds to the fastest conducting fibers. Conduction studies may therefore fail to show an abnormality in a disease that affects only small-diameter nerve fibers if surface recording methods are used. "Near nerve" recording, however, can assess these slower components of the sensory response from smaller diameter myelinated fibers. Direct recording from the smallest myelinated and unmyelinated fibers is called "micro-neurography."

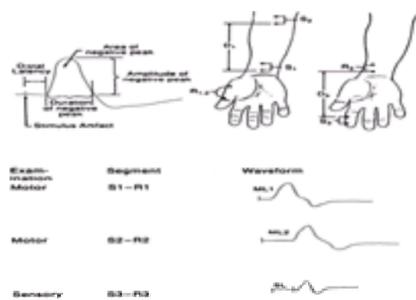

FIG. 15.1. Technique for motor and sensory conduction studies of the median nerve. **A:** Components of the evoked compound muscle action potential. **B:** Electrode placement for motor nerve stimulation (S1, S2) and recording (R1, R2). **C:** Electrode placement for sensory nerve stimulation (S3) and recording (R3). S1, motor stimulation at wrist; S2, motor stimulation at elbow; S3, sensory stimulation at finger; R1, motor response after stimulation at S1; R2, motor response after stimulation at S2; R3, sensory nerve evoked response after stimulating finger; ML, motor latency or the time between onset of stimulation and onset of motor response; SL, sensory latency or the time between onset of stimulus to onset of sensory response.

The distal motor latency is the time between the onset of the stimulus and the onset of the muscle response. Stimulation at a more proximal point produces an evoked response with a longer latency (proximal latency). Both distal and proximal motor latencies include the time needed to cross the neuromuscular junction. Therefore, when the distal latency is subtracted from the proximal latency, the effect of neuromuscular transmission is eliminated, and the resulting time represents the speed of conduction of the nerve in that specific segment. The distance between the two points of nerve stimulation is measured to calculate segmental conduction velocity (distance/latency difference = velocity). In contrast, sensory nerve conduction in peripheral nerve does not involve synaptic transmission, so velocity measurements are calculated directly from the distance and latency ([Fig. 15.1](#)).

Conduction velocity is determined by the size of the largest diameter (and therefore fastest conducting) axon and the presence of normal myelin, the component of peripheral nerves that provides the structural basis for saltatory conduction. In demyelinating diseases, the segmental velocity slows to approximately half of the normal mean. In axonal disease, if the large-diameter fibers are preferentially lost, velocity can also slow but not to less than 50% of the normal mean.

The evoked response has a biphasic (motor) or triphasic (sensory) waveform. The size of the evoked response depends on the number of fibers activated under the electrode, the surface area of the electrode, and the synchrony of firing. If the firing of motor nerve fibers is well synchronized, the muscle response is also synchronized, and the duration of the muscle evoked response is short. If nerve conduction is pathologically slow, nerve fibers that conduct at different speeds may be affected differently, resulting in poorly synchronized arrival of nerve impulses to the muscles, and duration of the waveform increases and the amplitude decreases because of phase cancellation between individual action potentials. In chronic partial denervation, individual axons are not all affected to the same extent, and reinnervation augments the dispersion of conduction velocities. Therefore, in chronic neuropathy or motor neuron disease, proximal stimulation may evoke a response of lower amplitude than distal stimulation even though the same number of fibers is activated.

The excessive loss (>50%) of amplitude between two points of stimulation is a suspicious sign of conduction block, which is pathognomonic of a demyelinating neuropathy ([Fig. 15.2](#)). In chronic partial denervation, however, the lower evoked response amplitude may only be due to phase cancellation and temporal dispersion. To differentiate the effects of temporal dispersion from conduction block in chronic partial denervation, the area under the negative phase is measured. Computerized models of conduction in the rat sciatic nerve suggest that a loss of more than 50% of the area of the response indicates that both temporal dispersion and conduction block are present.

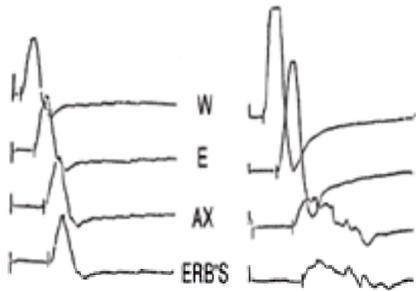

FIG. 15.2. Motor conduction block. **A:** Normal. Evoked compound muscle action potential amplitude shows little change at all points of stimulation. (Calibration, 1 cm = 10 mV.) **B:** Conduction block with amplitude reduction and temporal dispersion in the nerve segment between axilla and elbow. (Calibration, 1 cm = 5 mV.) W, wrist; E, elbow; Ax, axilla; Erb's, Erb's point.

If both distal and proximal stimulation result in a response of low amplitude, the pattern implies a diffuse (proximal and distal) process and a generalized loss of axons, as in an axonal neuropathy. Axonal neuropathies usually show normal distal motor latency, normal or borderline normal segmental velocity, no conduction block, or dispersion. Demyelinating neuropathies show prolonged distal latency, slow segmental velocity, normal or reduced evoked response amplitude, conduction block, and increased temporal dispersion.

F response and H reflexes evaluate conduction in the proximal portions of nerve fibers. The F response, so named because it was first observed in small foot muscles, is a measure of conduction along the entire length of nerve from the distal point of stimulation to the anterior horn cells and back to the distal recording electrode. This technique uses the same recording setup as standard motor nerve conduction studies except that the stimulator is rotated 180 degrees (cathode proximal). Normal values depend on limb length but are usually less than 32 ms in the arms and 60 ms in the legs. The waveform is characteristically present at supramaximal stimulation and varies in latency, shape, and presence. Although F responses are often prolonged in neurogenic conditions, they are of most value when distal conduction is normal; that is, if the F response latency is prolonged and velocity in distal segments is normal, slowing occurs in proximal segments. This pattern is seen in proximal polyradiculopathies, such as the Guillain-Barré syndrome. In chronic demyelinating neuropathies, the proximal segments may also be involved, and the F response latency may be longer than expected from the velocity calculated in distal portions.

The H reflex is considered to be the electrical counterpart of the Achilles reflex, although the pathways are not identical. The H reflex is sometimes seen in the absence of the Achilles reflex and vice versa. In contrast to the F response, which uses only the efferent motor nerve pathway, the H reflex is thought to be a monosynaptic reflex with an afferent and efferent limb. It is recorded from multiple muscles in infants, but as the nervous system matures, the H reflex is found only in the tibial nerve or soleus system (absent in 10% of normal subjects) or in the median nerve or flexor carpi radialis system. The H reflex occurs during submaximal stimulation, does not vary in shape, and disappears with supramaximal stimulation. It is one of the few measures of afferent nerve conduction in proximal portions of sensory nerves and identifies dorsal root pathology when the H reflex is prolonged in conjunction with normal F response latency in the same nerve. Additionally, the H reflex may "reappear" in muscle or nerve systems other than the tibial or soleus system as part of upper motor neuron diseases, such as multiple sclerosis or primary lateral sclerosis.

ELECTROMYOGRAPHY

The electrical activity of muscle may be recorded with surface electrodes, but spontaneous electrical activity (fibrillations and positive sharp waves) and individual voluntary motor units cannot be seen with surface electrodes. EMG is therefore performed with a needle electrode (either monopolar or concentric) placed directly in the muscle for extracellular recording of action potentials generated by the muscle fibers spontaneously or during voluntary movement. Needle recording can also be used to measure evoked potentials after motor nerve stimulation when the surface recorded potential is too low for reliable measurements. Needle recording of evoked potentials, however, is less reliable because the waveform is affected by movement of the activated muscle.

Diagnostic information includes the type and amount of spontaneous activity, evaluation of motor unit form with minimal volitional activity, and the density of motor units during maximal activation. After denervation, muscle fibers discharge spontaneously. These extracellular potentials recorded at rest are called positive sharp waves and fibrillation potentials. Although characteristic of denervating conditions (peripheral neuropathy, traumatic neuropathy, plexopathy, radiculopathy, and motor neuron disease), spontaneous potentials are also seen in some myogenic disorders (polymyositis and even in dystrophinopathies) but rarely in disorders of neuromuscular transmission (myasthenia gravis, Lambert-Eaton syndrome, and botulism). Fibrillation potentials are biphasic or triphasic and of short duration and are generated by discharges of single muscle fibers. Positive sharp waves are thought to have the same implications as fibrillation potentials but are differently shaped because the traveling wave terminates at the point of needle recording, so there is no upward negative phase.

Fasciculations are spontaneous discharges of an entire motor unit that comprise all the muscle fibers innervated by a single axon. The amplitude and duration of the fasciculation potential are therefore greater than the fibrillation. Fibrillations are never seen clinically, but fasciculations can usually be seen with the naked eye. Fasciculations are of neurogenic origin and are most often associated with proximal diseases, such as anterior horn cell disease or radiculopathy. They are occasionally found, however, in generalized peripheral neuropathy and even in normal individuals (benign fasciculations).

Other types of spontaneous activity include myotonia (high-frequency muscle fiber discharge of waxing and waning amplitude), complex repetitive discharges (which are spontaneous discharges of constant shape and frequency with abrupt onset and abrupt cessation), and myokymia and neuromyotonia (bursts of muscle activity that often, but not always, are associated with cramps and visible twitching). Clinically, these electrical phenomena occur in Isaac syndrome and myokymia. EMG is useful in the difficult clinical differentiation of facial myokymia and facial hemispasm.

Motor unit configuration changes depending on the particular disease. In neurogenic disease, the motor unit territory increases and the motor unit potentials increase in duration and amplitude. Standard monopolar and concentric needles record only from a portion of the motor unit, but the change in amplitude and duration is diagnostic. In myogenic disease, motor unit potentials decrease in amplitude and duration. Quantitative motor unit potential analysis provides more reliable correlation with muscle and nerve disease than muscle biopsy. Normal extracellularly recorded motor unit potentials are triphasic in shape; polyphasic motor units occur in both neurogenic and myogenic disease and are normally found in small numbers in all muscles. They are therefore nonspecific findings.

The recruitment pattern refers to the electrical activity generated by all activated motor units within the recording area of a maximally contracting muscle. Normally, the recruitment pattern on maximal effort is dense with no breaks in the baseline. The amplitude of the envelope (excluding single high-amplitude spikes) is normally 2 to 4 mV using a concentric needle with standard recording area (0.07 mm²). In neurogenic disease, the density of the recruitment is reduced and the firing frequency of the remaining units increases. Sometimes only one unit can be recruited by maximal effort, and this unit may fire faster than 40 Hz (discrete recruitment). In myogenic disease, the number of motor units is unchanged by the disease, but the amplitude and duration of the motor units are reduced. Therefore, recruitment density is normal, but the envelope amplitude is reduced, leading to the pathognomonic finding of myopathy: full recruitment in a weak wasted muscle.

NEUROMUSCULAR TRANSMISSION DISORDERS

Weakness occurs only if muscle fibers fail to contract or generate less than normal tension. Muscle fibers may fail to contract because of impaired nerve conduction, neuromuscular transmission, or muscle conduction. If muscle fibers are not activated because neuromuscular transmission fails, the abnormality is called blocking. If a sufficient number of muscle fibers is blocked, the amplitude of the evoked response is reduced. For example, in myasthenia gravis, repetitive electrical stimulation at 2 to 3 Hz causes progressive loss of the compound muscle action potential amplitude until the fourth or fifth response because of increasing numbers of neuromuscular junctions with blocking (Fig. 15.3). After the fifth potential, the compound muscle action potential usually shows no further decline or may slightly increase. Decrement also improves immediately after 10 to 15 seconds of intense exercise (postactivation facilitation; Fig. 15.3). If the muscle is exercised manually for 1 minute, the decrement becomes more pronounced at 3 to 4 minutes (postactivation exhaustion; Fig. 15.3).

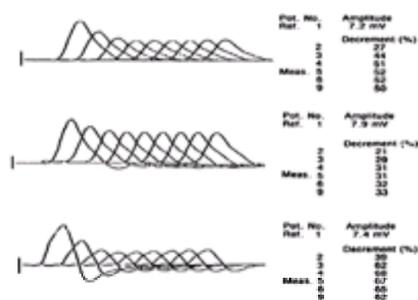

FIG. 15.3. Muscle action potentials evoked by repetitive stimulation at 3 Hz in myasthenia gravis. **A:** Showing decrement at rest. **B:** Postactivation facilitation. **C:** Postexercise exhaustion. (Calibration, 1 cm = 5 mV.)

In Lambert-Eaton syndrome and botulism, release of acetylcholine is impaired at rest, but during exercise or rapid rates of stimulation, acetylcholine release is facilitated. This is reflected by a positive edrophonium test and electrophysiologic decrement at low rates of stimulation and increment at fast rates.

Single-fiber EMG is a technique that identifies dysfunction of the muscle fibers before any blocking or overt weakness occurs (Fig. 15.4). When weakness appears, blocking is usually demonstrable. A normal single-fiber EMG study in a weak muscle rules out a disorder of neuromuscular transmission.

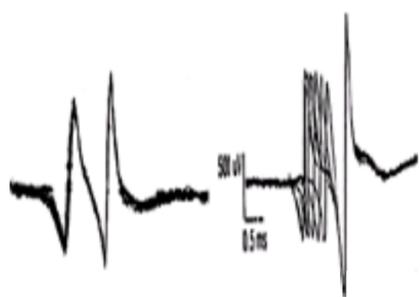

FIG. 15.4. Single-fiber EMG recordings showing normal **(A)** and increased **(B)** jitter.

CHAPTER 16. NEUROVASCULAR IMAGING

J. P. MOHR AND ROBERT DELAPAZ

[Computed Tomography](#)
[Magnetic Resonance Imaging](#)
[Magnetic Resonance Angiography](#)
[Catheter Angiography](#)
[Doppler Measurements](#)
[Regional Cerebral Blood Flow](#)
[Stable-Xenon Computed Tomography](#)
[Single Photon Emission Computed Tomography](#)
[Positron Emission Tomography](#)
[Discussion](#)
[Suggested Readings](#)

Brain imaging plays a central role in the diagnosis, classification, and prognosis of stroke. As technology advances, so do the applications. Conventional radiology plays little role now, and current techniques include computed tomography (CT) and magnetic resonance imaging (MRI) with or without contrast enhancement, MR diffusion and perfusion imaging, CT or MR angiography (MRA), ultrasonic Doppler insonation of blood flowing in the extra- or intracranial arteries and veins, MR spectroscopy (MRS), and single photon emission computed tomography (SPECT) by agents that assess blood flow or specific chemical reactions or receptors of the brain.

COMPUTED TOMOGRAPHY

Acute hematomas have a characteristic high-density (high-attenuation) appearance (bright) on CT in the first week; CT reliably differentiates the low-attenuation lesion (dark) typical of bland infarction from the high-attenuation of hematoma or grossly hemorrhagic infarction ([Fig. 16.1](#) and [Fig 16.2](#)). The volume of an acute parenchymal hematoma can be estimated accurately by CT. As the high signal of fresh blood is lost in days or weeks (hemoglobin breakdown) at the site, the CT appearance evolves from initial hyperdensity through an isodense (subacute) phase to hypodensity in the chronic state (see [Fig. 13.1](#)). In the subacute phase, contrast administration may result in ring enhancement around the hemorrhage ([Fig. 16.3](#)), a pattern different from the gyral enhancement typical of infarction ([Fig. 16.1](#)). This ring or rim enhancement may appear similar to tumor or abscess, a pitfall that is especially misleading with isodense or hypodense late hematomas. In the chronic state, a hematoma is usually reduced to a slitlike cavity after phagocytic clearing of hemorrhagic and tissue debris. Many hematomas disappear without creating a cavity, leaving isodense tissue. Subarachnoid hemorrhage is even more transient and may not be visible unless it is particularly dense; lumbar puncture can make the diagnosis of subarachnoid bleeding in those with normal CTs.

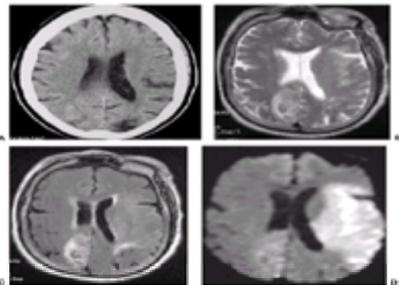

FIG. 16.1. Hyperacute cerebral infarct (3 hours). **A:** Axial noncontrast computed tomography appears normal except for the low density in the left medial parietal cortex representing a chronic infarct. **B:** Axial T2-weighted fast spin echo magnetic resonance (MR) image shows slight elevation of signal in the left insular cortex, high curvilinear signal at the deep margin of the chronic left parietal infarct, and high signal with central low signal in a subacute hemorrhagic infarct in the medial right parietal lobe. **C:** Axial fluid attenuated inversion recovery MR image shows slightly increased signal in the left periventricular region and high signal at the margin of the chronic infarct and mixed signal in the subacute infarct. **D:** Axial diffusion-weighted image ($b = 1,000$) shows a large region of high signal, representing low water proton diffusion rates, in the large middle cerebral artery infarct produced by carotid dissection 3 hours before the study. (Courtesy of Dr. R. L. DeLaPaz.)

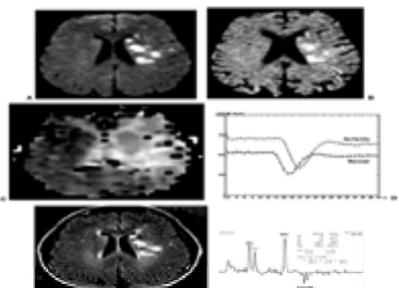

FIG. 16.2. Acute cerebral infarct (24 hours). **A:** Axial diffusion-weighted image (DWI, $b = 1,000$) shows a patchy region of high signal, representing low water proton diffusion rates, in an acute deep left basal ganglia and corona radiata infarct. **B:** The exponential apparent diffusion coefficient (ADC) map represents the ratio of signal on the DWI to the T2-weighted ($b = 0$) image. This map corrects for high signal on the DWI produced by high signal on the T2-weighted image, the T2 “shine through” effect. This acute infarct produces high signal on both the DWI and exponential ADC maps, confirming reduced tissue water diffusion. **C:** This map of relative perfusion delay, time to peak, was produced by rapid scanning with T2*-weighted images during an intravenous gadolinium contrast bolus injection. The high signal area in the region of the left-sided infarct represents a large zone of relatively delayed arrival of the peak signal change produced by the gadolinium bolus as it passes through the tissue capillary bed. **D:** The time-intensity curves show the transient drop in signal on T2*-weighted images as the gadolinium bolus passes through and indicate a substantial delay in the left-sided ischemic zone (9-second peak arrival delay; x-axis is image number with TR = 3 seconds and y-axis is signal intensity). **E:** Axial fluid attenuated inversion recovery magnetic resonance (MR) image shows patchy increased signal in the infarct. The square outline represents the voxel used for proton MR spectroscopy. **F:** Proton MR spectrum (TR 2,000, TE 144) shows a slight elevation of choline (Cho), a slight decrease in N-acetylaspartate (NAA), and a marked elevation of lactate (peak inversion is due to J-coupling of lactate doublet). Peak areas represent relative concentrations of tissue metabolites. (Courtesy of Dr. R. L. DeLaPaz.)

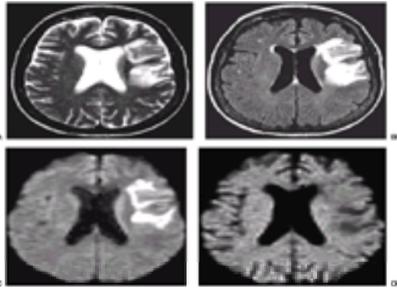

FIG. 16.3. Chronic cerebral infarct with T2 “shine through.” **A:** Axial T2-weighted fast spin echo (FSE) magnetic resonance (MR) image shows high signal in a chronic left middle cerebral artery (MCA) territory infarct. **B:** Axial fluid attenuated inversion recovery (FLAIR) MR image also shows high signal in the chronic left MCA territory infarct. **C:** Axial diffusion-weighted image (DWI, $b = 1,000$) shows a region of high signal corresponding to the MCA infarct and the high signal seen on the FSE and FLAIR images. **D:** The exponential apparent diffusion coefficient (ADC) map represents the ratio of signal on the DWI to the T2-weighted ($b = 0$) image. This map corrects for high signal on the DWI produced by high signal on the T2-weighted image, the T2 “shine through” effect. The exponential ADC map shows low signal in the lesion, indicating high water diffusion rates, as would be expected in a chronic infarct. Acute infarcts produce high signal on both the DWI and exponential ADC maps, indicating reduced tissue water diffusion (see [Fig. 16.2](#)). (Courtesy of Dr. R. L. DeLaPaz.)

With nonhemorrhagic infarction, CT may appear normal for several days. When there is collateral supply to the region, CT is usually positive within 24 hours, showing hypodensity due to edema. Ischemic infarcts with little collateral flow or edema may remain isodense or may not enhance for days or weeks, later appearing only as focal atrophy. Although CT may overestimate the size of deep lesions, it better approximates the volume of discrete surface infarcts, especially after several months when the acute effects of edema and necrotic tissue reabsorption have subsided ([Fig. 16.4](#)). Contrast-enhanced infarction is usually seen within 1 week and may persist for 2 weeks to 2 months. A characteristic gyriform enhancement pattern is often seen when cortical gray matter is involved.

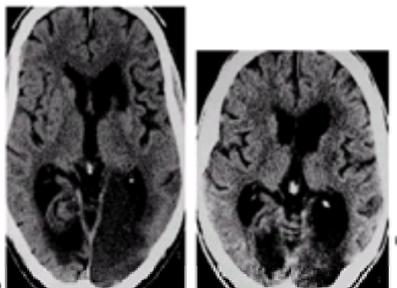

FIG. 16.4. Cerebral infarction, acute and chronic phases. **A:** Axial noncontrast computed tomography reveals focal regions of discrete lucency in left basal ganglia and right occipital regions without mass effect, suggesting nonacute infarcts. A “fainter” less well-defined left occipital lucency is also noted, with effacement of cortical sulci and the atrium of the ventricle, suggesting more recent infarction. **B:** Follow-up noncontrast scan 2 months later demonstrates interval demarcation of the left occipital infarct with evidence of focal atrophy, “negative mass effect” on the atrium, which appears larger. Similar change is noted in left frontal horn. (Courtesy of Drs. J. A. Bello and S. K. Hilal.)

Standard CT techniques do not distinguish partial ischemia from actual infarction. In the early stages, the physician may be frustrated by the difficulty determining how much tissue is viable and how much damage is permanent. Spiral CT provides serial scans during the first pass of an intravenous contrast bolus and can give relative measures of ischemia from derived blood volume and perfusion delay maps. Stable xenon-enhanced CT may also be useful.

Spiral CT can also scan the entire neck or head with a bolus intravenous infusion of contrast agent for a “CT angiogram.” Maximum intensity projection reformations, often with three-dimensional surface shading, display vascular features such as stenosis or aneurysm. Advantages of CT angiogram over catheter angiography include more widely available technology, less specialized skill requirements, and relatively noninvasive intravenous administration of contrast material. However, use of CT angiogram has been growing slowly because of competition from MRA. In contrast to MRA, the iodinated contrast agent is potentially more toxic because of allergic reactions, direct cardiac volume stress, or renal toxicity. Another limitation of CT angiogram is the time-consuming postprocessing required to edit out bone and calcium and to generate three-dimensional surface rendering.

Within the brain, CT may differentiate abnormal from normal soft tissues, particularly after intravenous administration of iodinated contrast agents; abnormal enhancement implies a breakdown of the blood–brain barrier. MRI is more sensitive than CT in demonstrating parenchymal abnormalities and can also be augmented by a contrast agent, gadolinium.

MAGNETIC RESONANCE IMAGING

MRI is rapidly overtaking CT in imaging of both hemorrhagic and ischemic stroke. The physics of MRI are discussed in [Chapter 13](#). Selection of the pulse sequence and plane of imaging is necessary to achieve the maximum utility of the technique. To diagnose and date hemorrhage, T1- and T2-weighted images are necessary ([Fig. 13.1](#) and [Fig. 16.5](#)). The appearance of parenchymal hemorrhage on MRI is much more complicated than on CT and varies as the hemorrhage evolves. Hyperacute hemorrhage, within the first 12 to 24 hours, usually appears as isointense to slightly hypointense on T1-weighted images and isointense to hypointense on T2-weighted images (also hypointense on fluid attenuated inversion recovery [FLAIR] and gradient echo [GRE] images). This pattern arises because a clot is first composed of intact red blood cells with fully oxygenated hemoglobin, giving it the same signal characteristics as brain tissue. Rapid deoxygenation generates deoxyhemoglobin, which is paramagnetic and produces low signal on T2-weighted images (shortens T2 relaxation) with little effect on T1-weighted images. After this hyperacute period, the hemoglobin within the red cells evolves into methemoglobin, which has a stronger paramagnetic effect and produces high signal on T1-weighted images (shortens T1 relaxation) with persistent low signal on T2-weighted images. After several days, the red cells break down in the subacute hematoma, resulting in a more uniform distribution of methemoglobin and dominance of the shortened T1 relaxation time, producing high signal on both T1-weighted and T2-weighted images. This appearance remains stable for weeks to months until the hemorrhagic debris is cleared by phagocytes, leaving only hemosiderin at the site of the hemorrhage. The chronic hemorrhagic site is isointense on T1-weighted images and hypointense to isointense on T2-weighted images. GRE images are especially sensitive to hemosiderin deposits and often show sites of chronic hemorrhage as low signal when both T1-weighted and T2-weighted images are isointense. GRE images are particularly useful as a screen for occult prior hemorrhage associated with suspected vascular malformations, amyloid angiopathy, trauma, or anticoagulation.

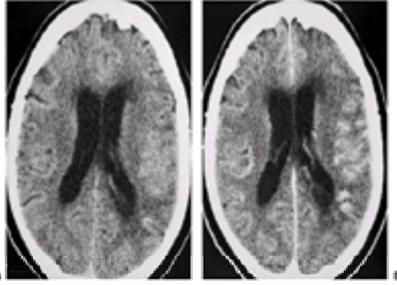

FIG. 16.5. Hemorrhagic infarction. **A:** Axial precontrast computed tomography shows focal left parietal gyral density consistent with hemorrhagic infarction. Note edema and sulcal effacement in left frontoparietal cortical region. **B:** Postcontrast enhancement in area of recent hemorrhagic infarction. (Courtesy of Drs. J. A. Bello and S. K. Hilal.)

The appearance of subarachnoid and other extraaxial hemorrhage follows similar stages of signal change but may evolve more rapidly or slowly, depending on location and cerebrospinal fluid dilution effects. The diagnosis of acute subarachnoid hemorrhage is still made most reliably with CT; recent experience with FLAIR indicates a high sensitivity to subarachnoid hemorrhage. FLAIR may identify subarachnoid hemorrhage as abnormal high signal in sulci that appear normal on CT. However, this high signal is less specific than high density on CT and may also represent cells or elevated protein content in cerebrospinal fluid caused by infection or meningeal neoplasm. GRE images are not sensitive or specific for acute subarachnoid hemorrhage but may show signs of repeated prior subarachnoid hemorrhage as low signal along the pial surface caused by deposition of hemosiderin (“hemosiderosis”).

MRI is unquestionably more sensitive and more specific than CT for the diagnosis of acute brain ischemia and infarction. The multiplanar capability, lack of artifact from bone, and the greater sensitivity to tissue changes provide MRI a particular advantage over CT for imaging infarcts in the brainstem (Fig. 16.6). Diffusion weighted imaging (DWI), described in more detail in Chapter 13, has revolutionized acute infarct detection. Severe cerebral ischemia and infarction cause a rapid decrease in intracellular diffusion that consistently produces high signal on DWI within minutes of cell injury. T2-weighted and FLAIR images show high signal in acute infarction only after a delay of 6 to 12 hours. DWI is also more specific for acute infarction. High signal lesions on FLAIR or T2-weighted images may represent acute, subacute, or chronic infarction, whereas the DWI shows high signal only in acute lesions. After the initial reduction in diffusion, there is a gradual rise through normal to prolonged diffusion rates during the 1 to 2 weeks after infarction, as cells disintegrate and freely diffusable water dominates the encephalomalacic tissue. A minor pitfall of DWI in subacute infarcts is the phenomenon called “T2 shine through,” where high signal on T2-weighted images may produce high signal on DWI, falsely indicating reduced diffusion. This pitfall can be avoided by the use of calculated apparent diffusion coefficient maps. DWI has become an essential part of acute stroke imaging and, because it takes less than a minute to acquire a whole brain study, is being used for screening a variety of clinical presentations for possible ischemic injury.

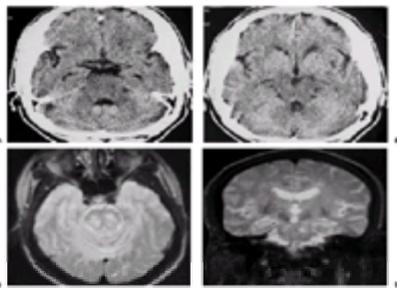

FIG. 16.6. Brainstem infarction. Noncontrast axial computed tomographies reveal possible infarcts in left brachium pontis (**A**) and right midbrain (**B**). Axial (**C**) and coronal (**D**) T2-weighted magnetic resonance scans of the same patient clearly show these and additional small infarcts not seen on CT. (Courtesy of Drs. J. A. Bello and S. K. Hilal.)

MRI methods for assessing cerebral perfusion, described in more detail in Chapter 13, have also transformed the evaluation of acute cerebral ischemia. Tissue blood flow is most commonly imaged with MRI using a “first pass” or “bolus tracking” method that records the signal changes that occur when rapidly repeated images are acquired during the first passage of an intravascular bolus of paramagnetic contrast material through the brain, usually gadolinium-diethylenetriamine pentaacetic acid. This rapid imaging can be done during routine contrast administration, adding minimal time to the routine examination. This method provides maps of relative cerebral blood volume, cerebral blood flow, and bolus mean transit time or time to peak. Measures of perfusion delay such as mean transit time and time to peak are proving to be sensitive indicators of subtle reductions in cerebral perfusion. A second method of MR perfusion imaging is called “spin tagging” or “time of flight” imaging and, like time-of-flight MRA, depends on T1 relaxation and flow enhancement phenomena without the use of injected contrast agents. This method is less widely used than bolus tracking but is capable of giving more quantitative cerebral blood flow measurements but with more limited coverage of the brain. These methods can be used to identify relatively underperfused brain regions distal to arterial stenoses or occlusions. They can also give an indication of the potentially salvageable “penumbra” of ischemic, but not yet infarcted, brain around an infarction, as indicated by high signal on DWI.

MRS (also described in Chapter 13), using either proton (^1H) or phosphorus (^{31}P), has limited application in the evaluation of acute ischemia. Although changes characteristic of injured or dead tissue can be seen, such as reduced *N*-acetylaspartate and elevated lactate on proton MRS and reduced energy metabolites on phosphorus MRS, the long duration (3 to 20 minutes) and low resolution (2 to 8 cm voxel size) of these methods limit practical application in the acute stroke patient. Proton MRS may be helpful with enhancing subacute infarction in deep white matter where routine imaging may suggest primary brain tumor. Although both infarct and tumor may show reduced *N*-acetylaspartate and elevated lactate, a markedly elevated choline peak is strong evidence for tumor and against infarction. Adding DWI may also be helpful because diffusion rates are usually normal to prolonged in tumor (iso to low signal on DWI) in contrast to low diffusion rates in acute to subacute infarction (high signal on DWI).

MAGNETIC RESONANCE ANGIOGRAPHY

MRA, also described in Chapter 13, is rapidly becoming the method of choice for screening the extracranial and intracranial vasculature. MRA, with Doppler ultrasound, is commonly used for the initial evaluation of carotid bifurcation stenosis. Depending on the institution and surgeon, these may be the only preoperative imaging studies done. Although MRA generally depicts a similar degree of stenosis to that on the Doppler ultrasound, there are artifacts on MRA that can be misleading. High flow rates can produce signal loss within the lumen, exaggerating the degree of stenosis, and turbulent flow can mimic complex plaque anatomy or ulceration. When the MRA and Doppler disagree substantially, catheter angiography is indicated for a definitive diagnosis.

MRA is also used for screening the intracranial circulation. Large vessels of the circle of Willis can be imaged effectively and rapidly, but current resolution precludes detailed observation of vessels more distal than the second-order branches of the middle cerebral artery. Conventional angiography remains the gold standard for evaluation of subtle segmental stenoses produced by arteritis, especially in small distal branches. Although MRA images are not as sharp as those of conventional angiography, all vessels are visualized simultaneously and can be viewed from any angle; most important, MRA is completely safe, noninvasive, and can be added to the routine MRI examination. The use of MRA as a screening technique for intracranial aneurysms is also increasing. Although MRA can detect aneurysms as small as 3 mm under optimal conditions, a practical lower limit in clinical usage is probably 5 mm diameter. A pitfall with time-of-flight MRA is the high signal produced by subacute parenchymal or subarachnoid hemorrhage that can mimic an aneurysm or AVM. Phase contrast MRA may be a better choice in patients with known hemorrhage. Conventional angiography is the definitive examination for evaluation of intracranial aneurysms and arteriovenous malformations. Other indications for

screening MRA include stroke, transient ischemic attack, and possible venous sinus thrombosis.

CATHETER ANGIOGRAPHY

Analysis of cerebrovascular disease has become increasingly precise with new technologies. As a result, many changes have occurred in practice, especially in the use of cerebral catheter angiography, once the mainstay of vascular imaging. Before the availability of CT and MRI, angiography was used routinely to outline intra- and extraaxial hematomas, evaluate vasospasm after ruptured aneurysms, and estimate degree of extracranial arterial stenosis. With the advent of CT, MRI, and Doppler studies, the diagnostic role of angiography is now more restricted. In many centers, angiography is used only to study intracranial vascular disease that is not visualized by MRI, MRA, or Doppler techniques. Catheter angiography involves the intraarterial injection of water-soluble iodinated contrast agents; transient opacification of the arterial lumen is filmed by conventional radiographic or digital subtraction techniques. Angiography is unsurpassed in the detailed anatomic depiction of stenosis, occlusion, recanalization, ulceration, or dissection of large and small intra- and extracranial arteries ([Fig. 16.7](#)).

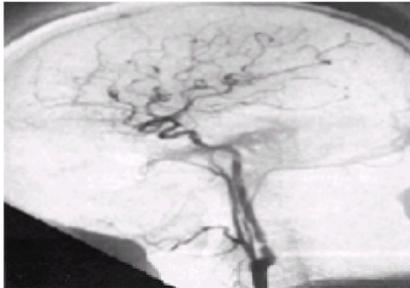

FIG. 16.7. Proximal internal carotid stenosis. Lateral arteriogram of the common carotid shows an ulcerated plaque of the proximal internal carotid with hemodynamically significant stenosis. Anterior circulation failed to fill and cross-filled from the contralateral side. (Courtesy of Drs. J. A. Bello and S. K. Hilal.)

Because catheter angiography is expensive, requires specialized catheter skills, and carries a 0.5% to 3% risk of embolic stroke, it is often undertaken only once in the course of hemorrhage or infarct evaluation. For a diagnosis of embolism, angiography should be carried out within hours of the ictus because the embolic particle may fragment early, changing the appearance of the affected vessel from occlusion to stenosis or a normal lumen, depending on the delay time. When atherosclerotic stenosis of large arteries is suspected, preangiographic studies of central retinal artery pressure or Doppler ultrasound (see the following) help to tailor the angiographic study and enable the angiographer to concentrate on the major territories thought to be affected. Catheter angiography is the primary method for preoperative evaluation of intracranial aneurysms and arteriovenous malformations, especially if interventional catheter therapies are being considered.

Catheter angiography techniques have become more sophisticated and now include interventional methods for the treatment of neurovascular disease. Thrombolytic agents can be delivered directly to intravascular clots, including higher order intracranial vessel branches using superselective microcatheter techniques and to major dural sinuses using retrograde venous approaches. Arterial stenosis can be treated with angioplasty, which involves catheter placement of an intravascular balloon at the stenotic site and then inflating the balloon to expand the vessel. Angioplasty is used mostly for atherosclerotic disease in the extracranial vessels, sometimes followed by placement of a wire mesh stent to help keep the lumen patent. Angioplasty is also used to expand a stenosis caused by vasospasm with subarachnoid hemorrhage. Occlusion of abnormal vessels and aneurysms can also be performed using intravascular techniques. Arteriovenous malformations and fistulas can be treated by occlusion of the feeding arteries with coils (flexible metal spiral coils that induce local thrombosis), and the AVM nidus can be occluded with bucrylate, a rapidly setting polymer glue. Aneurysms can be treated by catheter placement of coils and occasionally balloons within them when surgical treatment is not feasible because of aneurysm anatomy, location, or the patient's medical status. Emergency arterial occlusions are also performed for uncontrollable epistaxis and postoperative hemorrhage in the neck, paranasal sinus, and skull base regions.

DOPPLER MEASUREMENTS

The simplest Doppler devices pass a high-frequency continuous wave sound signal over the tissues in the neck, receive the reflected signal, and process them through a small speaker. Technicians using a *continuous wave Doppler* listen for the pitch of the sound and make a rough judgment of the degree of the Doppler shift to infer whether the blood moving through the artery beneath the probe is normal, decreased, or increased and, if increased, whether blood flow is smooth or turbulent. Little experience is required to separate the high-frequency arterial signal from the low-frequency venous sound or to recognize the extremely high frequencies of severe stenosis. More effort is required to quantitate the signal for comparison with a test at a later date. Because the Doppler shift equation depends on the cosine of the beam versus the flowing blood within the artery, casual angulation of the probe can have major effects on signal production.

To assist in proper probe angulation, *duplex Doppler* devices have two crystals, one atop the other, in a single probe head; one crystal handles the Doppler shift for spectral analysis and the other, the B-mode image of the vessel walls. Improvement in crystal designs have reduced the size of the probe, but it is still so bulky that it is difficult to image and insonate the carotid artery high up under the mandible. The Doppler shift crystal has an adjustable range gate to permit analysis of flow signals from specific depths in the tissues, eliminating conflicting signals where arteries and veins overlie one another. Some even have two range gates, providing an adjustable "volume" or "window" to insonate the moving blood column in an artery at volumes as small as 0.6 mm, the size of the tightest stenosis. The capacity to interrogate the flow pattern from wall to wall across the lumen has made this technique useful for detecting, measuring, and monitoring degrees of stenosis ([Fig. 16.8](#)). Because duplex Doppler is sensitive to cross-sectional area and not to wall anatomy, if it is used before angiography, it can alert the angiographer to seek stenotic lesions that might be missed on a survey angiogram. Unfortunately, B-mode vessel imaging is insensitive to most minor ulcerations, which are better seen by conventional angiography. Although duplex Doppler methods were developed to insonate the carotid, they can assess the extracranial vertebral artery through the intervertebral foramina.

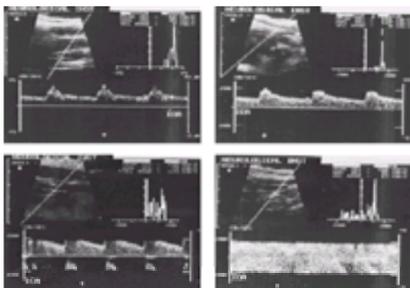

FIG. 16.8. Four studies, each showing different degrees of stenosis of the extracranial internal carotid. The studies, obtained with the Dasonics DRF 400 instrument, image the carotid by B-mode ultrasound (upper left-hand corner of each of the four pictures) by passing the ultrasound beam through the tissues (*angled line*) and sampling the flow velocity at a point within the lumen of the vessel (*horizontal bracketed line*). From this sample, the device displays the waveforms representing the velocity profile calculated from the Doppler shift (waveforms shown with velocity in cm/s in each picture). The mean velocities are then calculated from a sample taken near the peak of each waveform (small *arrow* under each waveform line) and the spectrum of velocities (i.e., degree of turbulence) is displayed as "peak vel" (i.e., velocity), "mean vel," and "vel range" (shown in graphic form in the upper right-hand corner of each picture). Examples of varying degrees of stenosis are shown: normal flow, left upper corner; moderate (60% to 80%) stenosis with moderate turbulence, right upper corner; severe (80% to 90%) stenosis with marked turbulence, left lower corner; extremely severe (90% to 99%) stenosis with extreme turbulence, right lower corner.

Using a probe with great tissue penetration properties, it is possible to insonate the major vessels of the circle of Willis, the vertebrals, and the basilar. Current transcranial Doppler devices are range gated, and the latest models give a color-coded display of the major intracranial arteries (Fig. 16.9). The signals accurately document the direction and velocity of the arterial flow insonated by the narrow probe beam. Spectrum analysis of the signal allows estimation of the degree of stenosis as does extracranial duplex Doppler. Hemodynamically important extracranial stenosis may damp the waveform in the ipsilateral arteries above, allowing the effect of the extracranial disease to be measured and followed serially. A challenge test of contralateral compression can be done to determine whether the effects of unilateral extracranial stenosis are compensated or lack anatomic collaterals. Care must be taken to determine which artery is being insonated; the middle cerebral and posterior cerebral are often misinsonated. The technique is user sensitive, requiring patience to detect the signal and then find the best angle for insonation at a given depth. Minor anatomic variations can cause misleading changes in signal strength. Because the procedure is safe, fast, and uses a probe and microprocessor of tabletop size, the device can be taken to the bedside even in an intensive care unit and used to diagnose developing vasospasm, collateral flow above occlusions, recanalization of an embolized artery, and the presence of important basilar or cerebral artery stenosis. When combined with MRI, it is possible to make a noninvasive diagnosis of stenosis of the basilar artery on the stem of the middle cerebral artery.

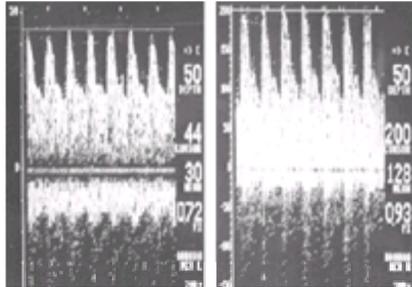

FIG. 16.9. Two examples of transcranial Doppler insonations of the middle cerebral artery, obtained at a depth of 50 mm from the side of the head overlying the temporal bone, using the Carolina Medical Electronics TC-64B device. The velocity profile of the Doppler shift is insonated at this depth from the blood in the middle cerebral artery flowing toward the probe (upper arrow directed to the right in each picture). The left picture shows a normal peak (cursor 44 [cm/s], left) and mean (30) and pulsatility index (0.72 PI, i.e., the difference between the peak systolic velocity and the end diastolic velocity divided by the mean velocity). Right: The peak (200 cursor) and mean (128 mean) velocities and the pulsatility index (0.93) are higher, consistent with local stenosis at this point in the course of the middle cerebral artery.

REGIONAL CEREBRAL BLOOD FLOW

This oldest and least expensive of the techniques uses ^{133}Xe , inhaled or injected, to generate precise measurements of cortical blood flow. This is one method that can be used at the bedside, in the operating room, or in the intensive care unit, but its spatial resolution is inferior to that of positron emission tomography (PET) or SPECT and it provides no information about subcortical perfusion. It is commonly used with hypercapnia or hypotension to test autoregulatory capacity of resistance vessels. For instance, focal failure of vasodilatory response, if distributed in the territory of a major vessel, has been taken as evidence of maximal dilatation and therefore reduced perfusion pressure. This finding is correlated with elevated cerebral blood volume by SPECT and oxygen extraction fraction by PET and may indicate hemodynamic insufficiency.

STABLE-XENON COMPUTED TOMOGRAPHY

CT can measure changes in tissue density over a period of minutes when nonradioactive xenon gas (essentially a freely diffusible high-attenuation contrast agent) is inhaled and circulates through the capillary bed. This method measures flow in both deep and surface structures at high resolution and provides automatic registration to the anatomic information in the baseline CT. It is limited by problems of signal-to-noise ratio and also by the physiologic and anesthetic effects of the high xenon concentrations (approximately 30%).

SINGLE PHOTON EMISSION COMPUTED TOMOGRAPHY

Like PET, SPECT consists of tomographic imaging of injected radioisotopes. However, these isotopes emit single photons rather than positrons, a difference that gives SPECT a more favorable cost-to-benefit ratio and makes it more widely available and clinically useful. However, SPECT is limited in application and is used widely only for imaging cerebral perfusion. Cerebral blood volume imaging is also available, and combined flow and volume scans are possible. Metabolic and receptor agents are being developed. SPECT imaging of infarction and ischemia appears to offer high sensitivity and early detection, but specificity is not yet established. In contrast to PET, SPECT can be used hours after an injection of the tracer; cerebral blood flow can be assessed under unique circumstances (e.g., during an epileptic seizure). Another promising use may be determination of cerebrovascular reserve through dilatory challenge (CO_2 or acetazolamide) or combined flow and volume imaging (Fig. 16.10). These techniques may identify the areas where blood flow is reduced because of perfusion pressure, and therefore possibly of causal relevance, as opposed to the areas where flow is reduced because of diminished metabolic demand (e.g., due to infarction) and therefore of less therapeutic significance. Similar to cardiac methods, these techniques may indicate regions of tissue viability.

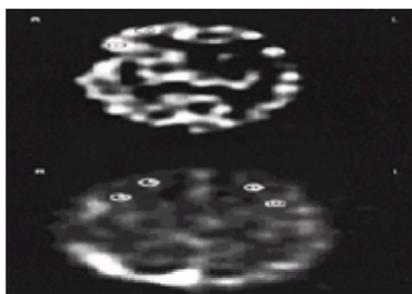

FIG. 16.10. Single photon emission computed tomography (SPECT) study of a 64-year-old woman after 2 weeks of progressive saltatory aphasia and right hemiparesis. The syndrome was attributed to a distal field infarct in the left hemisphere, and the left internal carotid artery was occluded. SPECT simultaneously imaged cerebral blood flow (CBF) with ^{123}I -IMP and cerebral blood volume (CBV) with $^{99\text{m}}\text{Tc}$ -labeled red blood cells. Top: CBF; bottom: CBV. Four areas of interest (A–D) were selected on the CBF image and samples on the CBV image. In the frontal cortex, blood flow was reduced and volume was increased on the left. The CBV/CBF ratio was 0.76 for A and D and 0.66 for B and C, thus implying a lower perfusion pressure on the left. (As is conventional for computed tomography and magnetic resonance imaging figures, the left side of brain is on the right of the figure.)

POSITRON EMISSION TOMOGRAPHY

PET generates axial images using physical and mathematical principles similar to those used in CT, but the source of radiation is internal to the imaged organ, originating in injected or inhaled radioisotopes. The radioisotopes are short lived and require an adjacent cyclotron. The expense and technical complexity limit the availability of PET. On the other hand, the biochemical flexibility and sensitivity of PET are unparalleled. PET is superior to any other technique in imaging specific

receptors or protein synthesis and turnover.

DISCUSSION

All these laboratory methods can be summarized with respect to their information content under four headings: vascular anatomy, tissue damage, hemodynamics, and biochemistry (Table 16.1). Although most techniques provide information in many domains, Table 16.1 indicates only the predominant applications. All cerebrovascular laboratory techniques can be assigned to one or more of the four main categories, but overlap is common and the boundaries are sometimes diffuse. For instance, tissue damage visualized by CT or MRI can be either hemorrhagic or ischemic infarction. Although the information may be useful in suggesting the more likely cause, vascular anatomy and local hemodynamics are usually more informative. For example, carotid occlusion or local absence of vascular reserve are two distinctly different causes of ischemic infarction and may lead to distinctly different treatment options. Finally, the assessment of local metabolism and biochemistry, best performed by PET and MRS, is not known to be clinically useful, but it is an area of active research.

- [Suggested Reading](#)

INDICATIONS

Lumbar puncture (LP) should be performed only after clinical evaluation of the patient and consideration of the potential value and hazards of the procedure. Cerebrospinal fluid (CSF) findings are important in the differential diagnosis of the gamut of central nervous system (CNS) infections, meningitis, and encephalitis and subarachnoid hemorrhage, confusional states, acute stroke, status epilepticus, meningeal malignancies, demyelinating diseases, and CNS vasculitis. CSF examination usually is necessary in patients with suspected intracranial bleeding to establish the diagnosis, although computed tomography (CT), when available, may be more valuable. For example, primary intracerebral hemorrhage or posttraumatic hemorrhage is often readily observed with CT, thus making LP an unnecessary hazard. In primary subarachnoid hemorrhage, however, LP may establish the diagnosis when CT is falsely negative. LP can ascertain whether the CSF is free of blood before anticoagulant therapy for stroke is begun. (Extensive subarachnoid or epidural bleeding is a rare complication of heparin anticoagulation that starts several hours after a traumatic bloody tap. Therefore, heparin therapy should not commence for at least 1 hour after a bloody tap.) LP has limited therapeutic usefulness (e.g., intrathecal therapy in meningeal malignancies and fungal meningitis).

CONTRAINDICATIONS

LP is contraindicated in the presence of infection in skin overlying the spine. A serious complication of LP is the possibility of aggravating a preexisting, often unrecognized brain herniation syndrome (e.g., uncus, cerebellar, or cingulate herniation) associated with intracranial hypertension. This hazard is the basis for considering papilledema to be a relative contraindication to LP. The availability of CT has simplified the management of patients with papilledema. If CT reveals no evidence of a mass lesion or edema, then LP is usually needed in the presence of papilledema to establish the diagnosis of pseudotumor cerebri and to exclude meningeal inflammation or malignancy.

HAZARDS OF BLEEDING DISORDERS

Thrombocytopenia and other bleeding diatheses predispose patients to needle-induced subarachnoid, subdural, and epidural hemorrhage. LP should be undertaken only for urgent clinical indications when the platelet count is depressed to about 50,000/mm³ or below. Platelet transfusion just before the puncture is recommended if the count is below 20,000/mm³ or dropping rapidly. The administration of protamine to patients on heparin and of vitamin K or fresh frozen plasma to those receiving warfarin is recommended before LP to minimize the hazard of the procedure.

COMPLICATIONS

Complications of LP include worsening of brain herniation or spinal cord compression, headache, subarachnoid bleeding, diplopia, backache, and radicular symptoms. Post-LP headache is the most common complication, occurring in about 25% of patients and usually lasting 2 to 8 days. It results from low CSF pressures caused by persistent fluid leakage through the dural hole. Characteristically, the head pain is present in the upright position, promptly relieved by the supine position, and aggravated by cough or strain. Aching of the neck and low back, nausea, vomiting, and tinnitus are common complaints. Post-LP headache is avoided when a small styletted needle is used and if multiple puncture holes are not made. The management of the problem depends on strict bedrest in the horizontal position, adequate hydration, and simple analgesics. If conservative measures fail, the use of a "blood patch" is indicated. The technique uses the epidural injection of autologous blood close to site of the dural puncture to form a fibrinous tamponade that apparently seals the dural hole.

CEREBROSPINAL FLUID PRESSURE

The CSF pressure should be measured routinely. The pressure level within the right atrium is the reference level with the patient in the lateral decubitus position. The normal lumbar CSF pressure ranges between 50 and 200 mm (and as high as 250 mm in extremely obese subjects). With the use of the clinical manometer, the arterially derived pulsatile pressures are obscured, but respiratory pressure waves reflecting changes in central venous pressures are visible. Low pressures occur after a previous LP, with dehydration, spinal subarachnoid block, or CSF fistulas. Intracranial hypotension may be a technical artifact when the needle is not inserted in the subarachnoid space. Increased pressures occur in patients with brain edema, intracranial mass lesions, infections, acute stroke, cerebral venous occlusions, congestive heart failure, pulmonary insufficiency, and hepatic failure. Benign intracranial hypertension (pseudotumor cerebri) and spontaneous intracranial hypotension are discussed elsewhere.

CEREBROSPINAL FLUID CELLS

Normal CSF contains no more than 5 lymphocytes or mononuclear cells/mm³. A higher white cell count is pathognomonic of disease in the CNS or meninges. A stained smear of the sediment must be prepared for an accurate differential cell count. Various centrifugal and sedimentation techniques have been used. A pleocytosis occurs with the gamut of inflammatory disorders. The changes characteristic of the various meningitides are listed in [Table 17.1](#). The heterogeneous forms of neuro-AIDS are associated with a wide range of cellular responses. Other disorders associated with a pleocytosis include brain infarction, subarachnoid bleeding, cerebral vasculitis, acute demyelination, and brain tumors. Eosinophilia most often accompanies parasitic infections, such as cysticercosis, and may reflect blood eosinophilia. Cytologic studies for malignant cells are rewarding with some CNS neoplasms.

Meningitis	Appearance	Pressure	Protein	Glucose	Cells
Bacterial	Turbid	Increased	Increased	Decreased	Increased (neutrophils)
Viral	Clear	Normal	Normal	Normal	Increased (lymphocytes)
Fungal	Clear	Increased	Increased	Decreased	Increased (lymphocytes)
Parasitic	Clear	Normal	Normal	Normal	Increased (eosinophils)
Chemical	Clear	Normal	Increased	Normal	Increased (lymphocytes)

TABLE 17.1. CEREBROSPINAL FLUID FINDINGS IN MENINGITIS

Bloody CSF due to needle trauma contains increased numbers of white cells contributed by the blood. A useful approximation of a true white cell count can be obtained by the following correction for the presence of the added blood: If the patient has a normal hemogram, subtract from the total white cell count (cells/mm³) 1

white cell for each 1,000 red blood cells present. Thus, if bloody fluid contains 10,000 red cells/mm³ and 100 white cells/mm³, 10 white cells would be accounted for by the added blood and the corrected leukocyte count would be 90/mm³. If the patient's hemogram reveals significant anemia or leukocytosis, the following formula may be used to determine more accurately the number of white cells (W) in the spinal fluid before the blood was added:

$$W = \frac{\text{blood WBC} \times \text{CSF RBC}}{\text{blood RBC}} \times 100$$

The presence of blood in the subarachnoid space produces a secondary inflammatory response, which leads to a disproportionate increase in the number of white cells. After an acute subarachnoid hemorrhage, this elevation in the white cell count is most marked about 48 hours after onset, when meningeal signs are most striking.

To correct CSF protein values for the presence of added blood resulting from needle trauma, subtract 1 mg for every 1,000 red blood cells. Thus, if the red cell count is 10,000/mm³ and the total protein is 110 mg/dL, the corrected protein level would be about 100 mg/dL. The corrections are reliable only if the cell count and total protein are both made on the same tube of fluid.

BLOOD IN THE CEREBROSPINAL FLUID: DIFFERENTIAL DIAGNOSIS AND THE THREE-TUBE TEST

To differentiate between a traumatic spinal puncture and preexisting subarachnoid hemorrhage, the fluid should be collected in at least three separate tubes (the "three-tube test"). In traumatic punctures, the fluid generally clears between the first and the third collections. This change is detectable by the naked eye and should be confirmed by cell count. In subarachnoid bleeding, the blood is generally evenly admixed in the three tubes. A sample of the bloody fluid should be centrifuged and the supernatant fluid compared with tap water to exclude the presence of pigment. The supernatant fluid is crystal clear if the red count is less than about 100,000 cells/mm³. With bloody contamination of greater magnitude, plasma proteins may be sufficient to cause minimal xanthochromia, an effect that requires enough serum to raise the CSF protein concentration to about 150 mg/dL.

After an acute subarachnoid hemorrhage, the supernatant fluid usually remains clear for 2 to 4 hours or even longer after the onset of subarachnoid bleeding. The clear supernatant may mislead the physician to conclude erroneously that the observed blood is the result of needle trauma in patients who have had an LP within 4 hours of aneurysmal rupture. After an especially traumatic puncture, some blood and xanthochromia may be present for as long as 2 to 5 days. In pathologic states associated with a CSF protein content exceeding 150 mg/dL and in the absence of bleeding, faint xanthochromia may be detected. When the protein is elevated to much higher levels, as in spinal block, polyneuritis, or meningitis, the xanthochromia may be considerable. A xanthochromic fluid with a normal protein level or a minor elevation to less than 150 mg/dL usually indicates a previous subarachnoid or intracerebral hemorrhage. Xanthochromia may be caused by severe jaundice, carotenemia, or rifampin therapy.

Pigments

The two major pigments derived from red cells that may be observed in CSF are oxyhemoglobin and bilirubin. Methemoglobin is seen only spectrophotometrically. Oxyhemoglobin, released with lysis of red cells, may be detected in the supernatant fluid within 2 hours after subarachnoid hemorrhage. It reaches a maximum in about the first 36 hours and gradually disappears over the next 7 to 10 days. Bilirubin is produced in vivo by leptomeningeal cells after red cell hemolysis. Bilirubin is first detected about 10 hours after the onset of subarachnoid bleeding. It reaches a maximum at 48 hours and may persist for 2 to 4 weeks after extensive bleeding. The severity of the meningeal signs associated with subarachnoid bleeding correlates with the inflammatory response (i.e., the severity of the leukocytic pleocytosis).

Total Protein

The normal total protein level of CSF ranges between 15 and 50 mg/dL. Although an elevated protein level lacks specificity, it is an index of neurologic disease reflecting a pathologic increase in endothelial cell permeability. Greatly increased protein levels, 500 mg/dL and above, are seen in meningitis, bloody fluids, or spinal cord tumor with spinal block. Polyneuritis (Guillain-Barré syndrome), diabetic radiculoneuropathy, and myxedema also may increase the level to 100 to 300 mg/dL. Low protein levels, below 15 mg/dL, occur most often with CSF leaks caused by a previous LP or traumatic dural fistula and uncommonly in pseudotumor cerebri.

Immunoglobulins

Although many proteins may be measured in CSF, only an increase in immunoglobulins is of diagnostic importance. Such increases are indicative of an inflammatory response in the CNS and occur with immunologic disorders and bacterial, viral, spirochetal, and fungal diseases. Immunoglobulin assays are most useful in the diagnosis of multiple sclerosis, other demyelinating diseases, and CNS vasculitis. The CSF level is corrected for the entry of immunoglobulins from the serum by calculating the IgG index ([Table 17.1](#)). More than one oligoclonal band in CSF with gel electrophoresis (and absent in serum) is also abnormal, occurring in 90% of multiple sclerosis cases and in the gamut of inflammatory diseases.

Glucose

The CSF glucose concentration depends on the blood level. The normal range of CSF is between 45 and 80 mg/dL in patients with a blood glucose between 70 and 120 mg/dL (i.e., 60% to 80% of the normal blood level). CSF values between 40 and 45 mg/dL are usually abnormal, and values below 40 mg/dL are invariably so. Hyperglycemia during the 4 hours before LP results in a parallel increase in CSF glucose. The CSF glucose approaches a maximum, and the CSF-to-blood ratio may be as low as 0.35 in the presence of a greatly elevated blood glucose level and in the absence of any neurologic disease. An increase in CSF glucose is of no diagnostic significance apart from reflecting hyperglycemia within the 4 hours before LP.

The CSF glucose level is abnormally low (hypoglycorrhachia) in several diseases of the nervous system apart from hypoglycemia. It is characteristic of acute purulent meningitis and is a usual finding in tuberculous and fungal meningitis. It is usually normal in viral meningitis, although reduced in about 25% of mumps cases and in some cases of herpes simplex and zoster meningoencephalitis. The CSF glucose is also reduced in other inflammatory meningitides, including cysticercosis, amebic meningitis (*Naegleria*), acute syphilitic meningitis, sarcoidosis, granulomatous arteritis, and other vasculitides. The glucose level is also reduced in the chemical meningitis that follows intrathecal injections and in subarachnoid hemorrhage, usually 4 to 8 days after the onset of bleeding. The major factor responsible for the depressed glucose levels is increased anaerobic glycolysis in adjacent neural tissues and to a lesser degree by a polymorphonuclear leukocytosis. Thus, the decrease in CSF glucose level is characteristically accompanied by an inverse increase in CSF lactate level. A low CSF glucose with a decreased lactate level indicates impairment of the glucose transporter responsible for the transfer of glucose across the blood-brain barrier.

MICROBIOLOGIC AND SEROLOGIC REACTIONS

The use of appropriate stains and cultures is essential in cases of suspected infection. Tests for specific bacterial and fungal antigens and counterimmunoelectrophoresis are useful in establishing a specific cause. DNA amplification techniques using polymerase chain reaction have improved diagnostic sensitivity. Serologic tests on CSF for syphilis include the reagin antibody tests and specific treponemal antibody tests. The former are particularly useful in evaluating CSF because positive results occur even in the presence of a negative blood serology. There is no logical basis for applying specific treponemal antibody tests to CSF because these antibodies are derived from the plasma, where they are present in greater concentration.

CHAPTER 18. MUSCLE AND NERVE BIOPSY

ARTHUR P. HAYS

[Skeletal Muscle Biopsy](#)
[Peripheral Nerve Biopsy](#)
[Suggested Readings](#)

Biopsy of skeletal muscle or peripheral nerve is performed in patients with neuromuscular disorders, chiefly those with myopathy or peripheral neuropathy. At the least, the findings may indicate whether a syndrome of limb weakness is neurogenic or myopathic. This determination is made in conjunction with the findings on electromyography and nerve conduction studies; the interpretations based on biopsy and physiologic study are usually congruent with each other and also with clinical indicators from the history and examination. At best, the biopsy of muscle and nerve may give a specific tissue diagnosis. Sometimes, however, the findings are not diagnostic because the defining lesion has been missed in the biopsy, which is only a tiny sample of a voluminous tissue, and the lesions may be present in one area but not in another. Also, the pathologic changes may be too mild to distinguish from normal or too advanced to draw conclusions (“end-stage” muscle, for instance).

The yield of a specific diagnosis is low, but the percentage has increased through the application of technologic innovations. In myopathies, histochemical and immunohistochemical stains applied to frozen tissue sections and biochemical analysis of enzymes, structural proteins, or DNA have transformed the prospects of tissue-based diagnosis. Precise diagnoses in peripheral nerve disorders often require immunohistochemical stains to localize human antigens, resin histology (semithin plastic sections), electron microscopy, and teased preparations of myelinated nerve fibers.

The performance and analysis of a muscle and nerve biopsy are time-consuming and expensive. Therefore, the decision for biopsy is made only after a thorough evaluation that includes neurologic examination, family history, laboratory tests, cerebrospinal fluid examination, and electrodiagnostic studies. This workup obviates the need for biopsy in typical cases of myasthenia gravis, myotonic dystrophy, dermatomyositis, amyotrophic lateral sclerosis, Guillain-Barré syndrome, diabetic neuropathy, or any defined toxic neuropathy. Additionally, a rapidly expanding number of diseases can be diagnosed by DNA analysis of blood leukocytes without recourse to tissue analysis (e.g., McArdle disease, Duchenne or Becker muscular dystrophy, mitochondrial disorders, and Charcot-Marie-Tooth disease type IA, as described in [Chapter 84](#), [Chapter 96](#), [Chapter 102](#), and [Chapter 125](#)).

If a biopsy is deemed necessary, the neurologist should formulate a preliminary diagnosis and inform the pathologist to direct evaluation of the specimen most efficiently. The surgical procedure should be performed by an experienced neurologist or surgeon, identifying the tissue correctly and avoiding mechanically induced artifacts or insufficient quantity for examination. If special methods are not available locally, the service usually can be provided by a regional research center.

SKELETAL MUSCLE BIOPSY

Muscle biopsy is performed in patients with limb weakness, infantile hypotonia, exercise intolerance, myoglobinuria, or cramps. Evaluation should include serum creatine kinase assay, family history, and electromyography. A biopsy is also indicated in the final assessment of patients with a presumptive diagnosis of a muscular dystrophy, polymyositis, inclusion body myositis, congenital myopathy, or spinal muscular atrophy; glycolytic or oxidative enzyme defect; or myopathies associated with alcohol, electrolyte disturbance, drug toxicity, carcinoma, endocrine overactivity or underactivity, or long-term treatment with steroids. It is also justified in polymyalgia rheumatica and eosinophilic fasciitis and to show the extent of denervation associated with peripheral neuropathy in conjunction with sural nerve biopsy.

Muscles preferred for biopsy are the vastus lateralis, biceps, or deltoid in disorders of proximal limb weakness and the gastrocnemius, tibialis anterior, or peroneus brevis when symptoms are pronounced distally. The muscle should be affected clinically and electrophysiologically. However, to avoid obtaining an end-stage picture, the muscle should not be severely wasted and paralyzed.

Routine histology of muscle can demonstrate groups of atrophic myofibers in a neurogenic disorder or myopathic features that include necrotic fibers, regenerating fibers, excessive sarcoplasmic glycogen, or centrally located myonuclei. Lymphocytic infiltration of connective tissue is seen in dermatomyositis, polymyositis, and inclusion body myositis. The diagnosis of vasculitis or amyloidosis is occasionally established by finding changes in the muscle biopsy, even if neuropathy is evident clinically and physiologically.

Histochemical techniques applied to cryosections of muscle permit the recognition of fiber-type grouping; target fibers; fiber-type predominance; selective fiber atrophy; central cores; nemaline rods; excessive sarcoplasmic glycogen, lipid, or mitochondria (ragged red fibers) as a result of a disorder of metabolism; deficiency of phosphorylase, phosphofructokinase, adenylate deaminase, or cytochrome *c* oxidase activity; and other structurally specific abnormalities that are not visible by conventional light microscopy of paraffin-embedded tissue. An example is provided by the finding of rimmed vacuoles and the intracellular amyloid inclusions of inclusion body myositis.

Biochemical assays of muscle can detect a quantitative reduction of enzymes of intermediary metabolism, including enzymes of the glycolytic pathway, acid maltase, adenylate deaminase, and enzymes of mitochondria (carnitine palmitoyl transferase, enzymes of the citric acid cycle, and electron transport chain).

Immunohistochemical stains can detect the absence of dystrophin in Duchenne muscular dystrophy and a mosaic pattern of dystrophin in girls or women who carry the mutation. Discontinuities of sarcolemmal dystrophin are found in Becker dystrophy. These dystrophinopathies must be confirmed by DNA analysis of blood leukocytes or by electrophoresis of a muscle homogenate (Western blot) to show quantitative or qualitative abnormalities of the protein. Dystrophin analysis is indicated in any syndrome of limb weakness of unknown cause, including possible limb-girdle dystrophy, polymyositis, inclusion body myositis, myoglobinuria, or spinal muscular atrophy. Genetic lack of sarcoglycans, merosin, emerin, or other proteins can be demonstrated by immunohistochemistry in the appropriate muscular dystrophies and confirmed by DNA analysis. Also, evaluation of mitochondrial DNA of muscle or blood can detect deletions in Kearns-Sayre syndrome and point mutations in other mitochondrial encephalomyopathies.

PERIPHERAL NERVE BIOPSY

Nerve biopsy is indicated in patients with peripheral neuropathy when additional information about the nature and severity of the disorder is needed. The biopsy is most likely helpful in mononeuritis multiplex or in patients with palpably enlarged nerves; biopsy is often uninformative in distal symmetric axonal neuropathies. In children, the pathologic features in nerve can be diagnostic in three diseases (metachromatic leukodystrophy, adrenoleukodystrophy, and Krabbe disease), but the biopsy can usually be avoided by making a diagnosis with tests of a blood sample. Several central nervous system disorders are also expressed pathologically in nerve: neuronal ceroid lipofuscinosis, Lafora disease, infantile neuroaxonal dystrophy, and lysosomal storage diseases. The best source of tissue, however, is not a nerve but rather skin and conjunctiva, which may show distinctive features in terminal nerve fibers and skin appendages.

The human sural nerve is the most widely studied nerve in health and disease, and it is most frequently recommended for biopsy. If mononeuritis multiplex spares the sural nerve, other cutaneous nerves can be selected (e.g., a branch of the superficial peroneal nerve at the head of the fibula or the radial sensory nerve at the wrist). Motor nerve fibers can be examined specifically in a nerve that supplies a superfluous or accessory muscle, such as the gracilis muscle in the medial thigh. Neurologists often choose simultaneous biopsy of both sural nerve and gastrocnemius muscle in patients with neuropathy because vasculitis, amyloidosis, sarcoid, lymphoma, and other systemic disorders are focal and lesions may be encountered in either tissue. The muscle also can demonstrate the degree of denervation.

Diagnosis can often be established by microscopic examination of paraffin-embedded tissue in nine conditions: vasculitis, amyloidosis, leprosy, sensory perineuritis, cholesterol emboli, infiltration of nerve by leukemic or lymphoma cells, malignant angioendotheliomatosis (intravascular lymphoma), giant axonal neuropathy, or adult polyglucosan body disease. Amyloid deposits in plasma cell dyscrasia can be identified by antibodies to immunoglobulin light chains. Amyloid deposits in the familial neuropathy resulting from transthyretin mutations can be distinguished by antibodies to the mutant protein. Small cell lymphoma and chronic lymphocytic leukemia can be separated from inflammatory reactions by application of lymphocyte markers.

Most neuropathies do not have distinctive pathologic findings and usually require examination of semithin sections of epoxy-resin–embedded tissue. Teased nerve

fibers and electron microscopy are necessary to identify the focal thickening of myelin sheaths (*tomacula*) of hereditary neuropathy with liability to pressure palsy, and they can detect subtle degrees of demyelination, remyelination, or axonal degeneration and regeneration. These features occur in normal nerves with increasing age, and evaluation may require formal quantitative study (morphometry). Electron microscopy also demonstrates accumulation of neurofilaments, widened myelin lamellae, and various intracellular inclusions in neuropathies, and it is needed to assess unmyelinated nerve fibers.

Axonal neuropathy is recognized by marked depletion of fibers and interstitial fibrosis, with or without myelin debris or regeneration of axons. It is most likely caused by a toxic or metabolic disorder, such as alcoholism or diabetes. Other axonopathies include vasculitis, amyloidosis, paraneoplastic syndromes, and infection (including the distal symmetric neuropathy of AIDS). Segmental demyelination and remyelination, recognized by thinly myelinated fibers and onion bulbs, are most often the result of an immunologically mediated or hereditary neuropathy. If demyelination is not pronounced in semithin plastic sections, it may be proved by electron microscopy or analysis of teased myelinated nerve fibers. Sural nerve biopsy is recommended in all patients with a clinical diagnosis of chronic inflammatory demyelinating polyneuropathy to confirm the suspected demyelination before commencing therapy with intravenous gamma globulin, plasmapheresis, or steroids. The pathologic findings do not distinguish chronic inflammatory demyelinating polyneuropathy from Charcot-Marie-Tooth disease type I, but an acquired myelinopathy is favored by finding prominent variability of abnormalities among nerve fascicles, inflammatory infiltrates, and endoneurial edema. The neuropathies associated with IgM paraproteinemia and antibody to myelin-associated glycoprotein resemble chronic inflammatory demyelinating polyneuropathy clinically and pathologically; deposits of the C3 component of complement may be seen along the periphery of myelin sheaths, usually with IgM located at the same site. Other demyelinating neuropathies include diphtheria, hereditary disorders other than Charcot-Marie-Tooth disease type I, Guillain-Barré syndrome, and acute or chronic inflammatory neuropathies in the early phase of human immunodeficiency virus infection. The inflammatory neuropathies are multifocal, and the sural nerve may be normal or show only axonal degeneration.

Complications of sural nerve biopsy include annoying causalgia in about 5% of patients. Many patients experience twinges of pain when bending forward for several days caused by stretching of the nerve. All patients should anticipate permanent loss of discriminative sensation in the lateral border of the foot extending to the fifth toe, heel, and lateral malleolus. In weeks or months, however, the sensory symptoms subside completely or to a tolerable level.

CHAPTER 19. NEUROPSYCHOLOGIC EVALUATION

YAAKOV STERN

- [Strategy of Neuropsychologic Testing](#)
- [Test Selection](#)
- [Tests Used in a Neuropsychological Evaluation](#)
- [Referral Issues](#)
- [Expectations from a Neuropsychologic Evaluation](#)
- [How to Refer](#)
- [Suggested Readings](#)

Neuropsychologic testing is a valuable adjunct to neurologic evaluation, especially for the diagnosis of dementia and to evaluate or quantify cognition and behavior in other brain diseases. The tests are therefore important in research as well.

STRATEGY OF NEUROPSYCHOLOGIC TESTING

Conditions that affect the brain often cause cognitive, motor, or behavioral impairment that can be detected by appropriately designed tests. Defective performance on a test may suggest specific pathology. Alternately, patients with known brain changes may be assessed to determine how the damaged brain areas affect specific cognitive functions. Before relating test performance to brain dysfunction, however, other factors that can affect test performance must be considered.

Typically, performance is compared with values derived from populations similar to the patient in age, education, socioeconomic background, and other variables. Scores significantly below mean expected values imply impaired performance. Performance sometimes can be evaluated by assumptions about what can be expected from the average person (e.g., repeating simple sentences or simple learning and remembering).

Comparable data may not exist for the patient being tested. This problem is common in older populations or for those with language and cultural differences. This situation may be addressed by collecting “local norms” that are more descriptive of the served clinical population or by evaluating the cognitive areas that remain intact. In this way, the patient guides the clinician in terms of the level of performance that should be expected in possibly affected domains.

Other factors that also influence test performance must be considered, including depression or other psychiatric disorders, medication, and the patient's motivation.

Patterns of performance, such as strengths in some cognitive domains and weaknesses in others, have been associated with specific conditions based on empirical observation and knowledge of the brain pathology associated with those conditions. Observation of these patterns can aid in diagnosis.

TEST SELECTION

Neuropsychologic tests in an assessment battery come from many sources. Some were developed for academic purposes (e.g., intelligence tests), and others from experimental psychology. The typical clinical battery consists of a series of standard tests that have been proved useful and are selected for the referral issue. A trade-off exists between the breadth of application and ease of interpretation available from standard batteries and the ability to pinpoint specific or subtle disorders offered by more experimental tasks that are useful in research but have not been standardized.

Most tests are intended to measure performance in specific cognitive or motor domains, such as memory, spatial ability, language function, or motor agility. These domains can be subdivided (e.g., memory can be considered verbal or nonverbal; immediate, short-term, long-term, or remote; semantic or episodic; public or autobiographic; or implicit or explicit). No matter how focused a test is, however, multiple cognitive processes are likely to be invoked. An ostensibly simple task, such as the Wechsler Adult Intelligence Scale Digit Symbol—Coding subtest (using a table of nine digit—symbol pairs to fill in the proper symbols for a series of numbers), taps learning and memory, visuospatial abilities, motor abilities, attention, and speeded performance. In addition, tests can be failed for more than one reason: Patients may draw poorly because they cannot appreciate spatial relationships or because they plan the construction process poorly. Relying solely on test scores can lead to spurious conclusions.

TESTS USED IN A NEUROPSYCHOLOGICAL EVALUATION

Intellectual Ability

Typically, the Wechsler Adult Intelligence Scale-III (WAIS-III) or the Wechsler Intelligence Scale for Children-III is used to assess the present level of intellectual function. These tests yield a global intelligence quotient (IQ) score and verbal and performance IQ scores that are standardized, so that 100 is the mean expected value at any age with a standard deviation of 15. The WAIS-III also groups some of the subtests, based on “more refined domains of cognitive functioning,” into four index scales: Verbal Comprehension, Perceptual Organization, Working Memory, and Processing Speed. The index scales have the same psychometric properties as the traditional IQ scores.

The WAIS-III consists of seven verbal and seven performance subtests. Scaled scores range from 1 to 19, with a mean of 10 and a standard deviation of 3; the average range for subtest scaled scores is from 7 to 13 ([Table 19.1](#)).

Subtest	Description
Verbal Comprehension	Requires the examinee to identify objects and to describe their uses.
Block Design	Requires the examinee to copy a design made of blocks.
Digit Symbol	Requires the examinee to copy a design made of digits and symbols.
Information	Requires the examinee to answer questions about general knowledge.
Similarities	Requires the examinee to identify similarities between objects.
Letter-Number Sequencing	Requires the examinee to copy a sequence of numbers and letters.
Picture Completion	Requires the examinee to identify missing parts of a picture.
Object Assembly	Requires the examinee to assemble a picture from pieces.
Symbol Search	Requires the examinee to find a symbol among a group of symbols.
Visual Spatial	Requires the examinee to identify a picture among a group of pictures.
Matrix Reasoning	Requires the examinee to identify a missing part of a matrix.
Picture Arrangement	Requires the examinee to arrange pictures in a logical order.
Stroop Color	Requires the examinee to name the color of a word.
Stroop Word	Requires the examinee to read a word.
Trail Making	Requires the examinee to connect dots in a specific order.
WAIS-III	Composite score of all subtests.

TABLE 19.1. SUBTESTS OF THE WECHSLER ADULT INTELLIGENCE SCALE-III

The overall IQ score supplies information about the level of general intelligence, but the neuropsychologist is usually more interested in the “scatter” of subtest scores, which indicate strengths and weaknesses. The subtests are better considered as separate tests, each tapping specific areas of cognitive function. There are also other tests of general intelligence, including some that are nonverbal.

Memory

The subclassifications of memory have evolved from clinical observation and experimentation; most are important to the assessment ([Table 19.2](#)). Preservation of remote memories despite inability to store and recall new information is the hallmark of specific amnesic disorders. Other subclassifications are used to evaluate

different clinical syndromes.

Verbal and nonverbal	Memory for material that is or is not verbally encoded
Immediate, short-term, long-term, and remote	Length of time between exposure to material and recall. The length of time has implications for how the memory may be stored and retrieved
Semantic and episodic	Memory for meaningful knowledge, such as vocabulary or facts about the world, as opposed to memory for events
Public and autobiographic	Memory for public community-known events versus events that occurred in one's own life
Explicit and implicit	Memory tested on tasks that do not require conscious explicit recollection of events requires such as motor skills, perceptual skills, classical conditioning, or learned verbal tasks that demand explicit recall of prior information (such as recall or recognition tasks)
Working	Similar to what in the past has been called short-term memory, working memory operates as buffer for actively holding on to information, such as a telephone number or the name of a newly found disease. It is also important for tasks that require mental manipulation of information, such as multiple arithmetic problems. For many theorists, working memory also has a more important role as the work space where recalled information is actively used, recombined, and related to other information, allowing complex cognitive processes such as comprehension learning and reasoning to take place.

TABLE 19.2. TYPICAL SUBCLASSIFICATIONS OF MEMORY ADDRESSED BY NEUROPSYCHOLOGIC TESTS

Construction

Construction, typically assessed by drawing or assembly tasks, requires both accurate spatial perception and an organized motor response. The Block Design and Object Assembly subtests of the WAIS-R are examples of assembly tasks. In the Rosen Drawing Test, the patient is asked to copy 15 drawings that range in difficulty from simple shapes to complex three-dimensional figures. In addition to the scores these tests yield, the clinician attends to the patient's construction performance to determine factors that may underlie poor performance (e.g., a disorganized impulsive strategy may be more related to anterior brain lesions, whereas difficulty aligning angles may arise in parietal lobe injury).

Language

"Mapping" of different aphasic disorders to specific brain structures was one of the early accomplishments of behavioral neurology. In neuropsychologic assessment, this model is often followed. Comprehension, fluency, repetition, and naming are assessed in spoken or written language.

Perceptual

Neuropsychologists may provide a standardized version of the neurologists' perceptual tasks: double simultaneous stimulation in touch, hearing, or sight; stereognosis; graphesthesia; spatial perception; or auditory discrimination.

Executive

The ability to plan, sequence, and monitor behavior has been called "executive function." These functions, linked to the prefrontal cortex, rely on and organize other intact cognitive functions that are required components for performance. Formal tests of executive function may be divided into set switching and set maintenance. For set switching, the Wisconsin Card Sort uses symbols that can be sorted by color, number, or shape. Based only on feedback about whether each card was or was not correctly placed, the subject must infer an initial sort rule. At intervals, the sort rule is changed without the subject's knowledge; subjects must switch based only on their own observation that the current rule is no longer effective.

The Stroop Color-Word Test assesses set maintenance. The subject is given a series of color names printed in contrasting ink colors (e.g., the word "blue" printed in red ink) and is asked to name the color of the ink. The response set must be maintained while the subject suppresses the alternate (and more standard) inclination to read words without regard to the color of the print.

Motor

Tests of motor strength, such as grip strength, and of motor speed and agility, such as tapping speed and peg placement, establish laterality and focality of impairment. In some diseases, such as the dementia of AIDS, reduced motor agility is part of the diagnosis. Higher order motor tasks, such as double alternating movements or triple sequences, are used to assess motor sequencing or programming as opposed to pure strength or speed.

Attention

The ability to sustain attention is often tested by cancellation tasks in which the patient must detect and mark targets embedded in distractors or by reaction time tasks. Speed and accuracy are the outcome measures.

Mood

Mood may affect test performance. At minimum, the neuropsychologist notes the psychiatric history and probes for current psychiatric symptoms. Standardized mood rating scales are also available.

Clinical Observation

Along with the formal scores, testing affords an extensive period to observe the patient under controlled conditions. These clinical observations are valuable for diagnosis. Formal test scores capture only certain aspects of performance. The patient's problem-solving approach or the nature of the errors made can be telling. Also important in timed tasks is whether the patient can complete them with additional time or is actually incapable of solving them. Another important dimension is the ability to learn and follow directions for the many tests.

More subtle aspects of behavior include responses or coping abilities when confronted with difficult tasks, ability to remain socially appropriate as the session progresses, and the subjects' appreciation of their own capacities.

REFERRAL ISSUES

Neuropsychologic testing is useful for the diagnosis of some conditions and is a tool for evaluating or quantifying the effects of disease on cognition and behavior. The tests can assess the beneficial or adverse effects of drug therapy, radiation, or surgery. Serial evaluations give quantitative results that may change with time. In temporal lobectomy for intractable epilepsy, tests are required in presurgical evaluation to minimize the possibility of adverse effects. Specific referral issues are summarized in the following paragraphs.

Dementia

Testing can detect early dementing changes and discriminate them from "normal" performance; obtain information contributing to differential diagnosis either between dementia and nondementing illness, such as depression versus dementia, or between alternate forms of dementia (e.g., Alzheimer disease, dementia with Lewy bodies, or vascular dementia); or confirm or quantify disease progression and measure efficacy of clinical interventions.

Other Brain Disease

The effects of stroke, cancer, head trauma, or other conditions on cognitive function can be investigated. This typical reason for testing may be prompted by the patient's complaints. The evaluation helps to clarify the cause or extent of the condition.

Epilepsy

Testing is needed for presurgical evaluation, because lateralization of memory and language, as well as focality of cognitive impairments, is an important concern. Pre- and postoperative evaluations after other types of neurosurgery are also common.

Toxic Exposure

Testing can evaluate consequences of toxic or potentially toxic exposures, either on an individual basis or for particular exposed groups (e.g., factory workers). Exposures can include metals, solvents, pesticides, alcohol and drugs, or any other compounds that may affect the brain.

Medication

The potential effect of medications on the central nervous system can be evaluated in therapeutic trials or clinical practice. For example, in trials of agents to treat Alzheimer disease, neuropsychologic tests are typically primary measures of drug efficacy. In clinical practice, adverse or therapeutic effects of newly introduced medications can be evaluated.

Psychiatric Disorders

Testing can help in the differential diagnosis of psychiatric and neurologic disorders, especially affective disorders and schizophrenia.

Learning Disability

Testing will evaluate learning disabilities and the residua of these disabilities in later life. Behavioral disorders, attention deficit disorder, autism, dyslexia, and learning problems are common referral issues.

EXPECTATIONS FROM A NEUROPSYCHOLOGIC EVALUATION

The minimum that a neuropsychologic evaluation yields is an extensive investigation of the abilities of the patient. In these cases, although the studies do not lead to a definite diagnosis, they help to determine the patient's capacities, track the future, and advise the patient and family.

Sometimes the evaluation suggests that additional diagnostic tests would be useful. For example, if a patient's pattern of performance deviates substantially from that typically expected at the current stage of dementia, a vascular contribution may be considered. Similarly, evaluation can suggest the value of psychiatric consultation or more intensive electroencephalographic recording.

Many times the neuropsychologist can offer a tentative diagnosis or discuss the possible diagnoses compatible with the test findings. Neuropsychologic evaluation cannot yield a diagnosis without appropriate clinical and historical information. In the context of a multidisciplinary testing, however, it may provide evidence to confirm or refute a specific diagnosis. Testing might best be considered an additional source of information to be used by the clinician for diagnosis in conjunction with the neurologic examination and laboratory tests.

HOW TO REFER

The more information the examiner has at the start, the more directly the issues can be addressed. For example, if magnetic resonance imaging has revealed a particular lesion, tests can be tailored specifically. The examination is not an exploration of ability to detect a lesion, but a contribution to understanding the implications of the lesion. Similarly, the more explicit the referral question, the more likely the evaluation can yield useful information. A useful referral describes the differential diagnosis being entertained. Alternately, the neurologist or the family may simply want to document the current condition or explore some specific aspect of performance, such as language.

CHAPTER 20. DNA DIAGNOSIS

LEWIS P. ROWLAND

Suggested Readings

We are still in the midst of the whirlwind created by molecular genetics. A little more than a decade ago, the diagnosis of an inherited disease depended primarily on clinical recognition. For some diseases, biochemical tests were available that identified the disease by the excretion or storage of an abnormal metabolite or, best of all, by finding decreased activity of the responsible enzyme.

That was the era of biochemical genetics, and one of the clinical lessons we learned was the recognition of genetic heterogeneity. The same enzyme abnormality might be associated with totally different clinical manifestations. For instance, the original clinical concept of muscle phosphorylase deficiency was a syndrome of muscle cramps and myoglobinuria induced by exertion, usually starting in adolescence. Later, however, we recognized totally different disorders as manifestations of phosphorylase deficiency. Infantile and late-onset forms have symptoms of limb weakness but no myoglobinuria.

Biochemical analysis in these diseases, as described in the chapters on metabolic diseases, is still important. Even in those conditions (mostly autosomal recessive), however, evidence from DNA analysis now reveals that different point mutations can result in the same biochemical abnormality. Already, 16 mutations in the muscle phosphorylase gene are known. Moreover, DNA analysis of circulating white blood cells may obviate the need for muscle biopsy.

Also, we can now diagnose autosomal dominant diseases by DNA analysis. For some conditions, we are in the peculiar position of trying to decide whether the disease should be named according to the change in DNA or, as in the past, by the clinical features. The problem arises because of two kinds of genetic heterogeneity. One is called *allelic heterogeneity*, which results from mutations in the same gene locus on one or both chromosomes. As a result, more than one clinical syndrome can be caused by mutations in the same gene. Conversely, the second type is *locus heterogeneity*, that is, the same clinical syndrome may be caused by mutations in different genes on different chromosomes.

DNA analysis is used in either of two ways to diagnose an individual who is at risk. In one way, *haplotype analysis, gene tracking, or linkage analysis* is applied when linked markers indicate the region of the disease gene but the gene itself has not been identified. Under these circumstances, we depend on DNA “markers” that are “polymorphic,” that is, there are two alleles for the particular marker, and many individuals are heterozygous so that the marker is “informative.” Using a set of markers, investigators define different types, one pattern labeled A, another B, and so on, depending on the number of markers. In this way, maternal and paternal genes can be identified, and one pattern tracks consistently with the disease (phenotype). In this way, an asymptomatic individual or a carrier of the gene can be identified. The method was used fruitfully for the study of families with Huntington disease or Duchenne dystrophy, among others. Chromosome maps of neurologic diseases indicate which diseases are amenable to this approach.

Haplotype analysis, however, has several drawbacks as a diagnostic test. Most important, it cannot be used for an individual, only for families. Moreover, the family must include people who are both affected by the disease and also alive. The more, the better. For such late-onset or rapidly fatal diseases as Parkinson disease, amyotrophic lateral sclerosis, or Alzheimer disease, however, many affected individuals in a family are no longer alive; sometimes, no affected family member is alive, only those at risk. If DNA is available from only one affected person, the investigation should include samples from at least three generations. Moreover, the test is labor intensive and expensive. Therefore, banking of DNA from affected people in families with heritable diseases is important.

The second kind of DNA analysis is more precise and can be used for individuals who may have a particular disease. This analysis can be done when the gene has been cloned and sequenced so that point mutations can be identified. Other mutations of diagnostic value include deletions, insertions, amplifications, and trinucleotide repeats. The number of diseases so identified has increased vastly in the past decade and seems to be augmented daily. In the ninth edition of this book, we provided a list of 41 individual diseases. Now several hundred individual diseases are amenable to DNA diagnosis, and it would take a booklet to tabulate them one by one. Instead, they can be grouped into 22 broad clinical categories ([Table 20.1](#)). More information is given in the specific chapters about these diseases.

TABLE 20.1. DNA DIAGNOSIS IN NEUROLOGIC DISEASE

Cloning a gene has more than diagnostic value; for many of these diseases, candidate gene products were suggested because they were mapped close to the position of the disease gene, were then linked to the gene, and are presumed to account for the manifestations of the disease. These characteristics are described in the chapters on specific diseases.

As a result of both locus heterogeneity and allelic heterogeneity, several different types of syndromes have been identified. Relying on the molecular differences, there are seven different forms of spinocerebellar atrophy, SCA 1 through SCA 7. It is difficult for clinicians to communicate about numerical names like these, but no alternative is in sight unless clinical manifestations emerge to provide old-fashioned names for diseases (i.e., in plain words).

Another problem of nomenclature arises from the diverse clinical syndromes caused by similar mutations, such as expansion of trinucleotide repeats or mutations in ion channel genes. Although the molecular changes are similar, there is little clinical similarity, for instance, between hemiplegic migraine and periodic paralysis (except that they are intermittent).

At present, there are still major impediments to widespread applicability of DNA analysis for diagnosis. First, reimbursement for the test is not established in many parts of the United States or elsewhere. Second, as a result, a systematic development of diagnostic laboratories has not yet emerged, not even commercially. Consequently, testing is often left to research laboratories, which is an inefficient use of resources; finding the appropriate laboratory may be a problem for the clinician and the patients. In time, this should be corrected.

SECTION III. INFECTIONS OF THE NERVOUS SYSTEM

CHAPTER 21. BACTERIAL INFECTIONS

JAMES R. MILLER AND BURK JUBELT

[Acute Purulent Meningitis](#)
[Subacute Meningitis](#)
[Subdural and Epidural Infections](#)
[Rickettsial Infections](#)
[Other Bacterial Infections](#)
[Suggested Readings](#)

The parenchyma, coverings, and blood vessels of the nervous system may be invaded by virtually any pathogenic microorganism. It is customary, for convenience of description, to divide the syndromes produced according to the major site of involvement. This division is arbitrary because the inflammatory process frequently involves more than one of these structures.

Involvement of the meninges by pathogenic microorganisms is known as *leptomeningitis*, because the infection and inflammatory response are generally confined to the subarachnoid space and the arachnoid and pia. Cases are divided into acute and subacute meningitis, according to the rapidity with which the inflammatory process develops. This rate of development, in part, is related to the nature of the infecting organism.

ACUTE PURULENT MENINGITIS

Bacteria may gain access to the ventriculosubarachnoid space by way of the blood in the course of septicemia or as a metastasis from infection of the heart, lung, or other viscera. The meninges may also be invaded by direct extension from a septic focus in the skull, spine, or parenchyma of the nervous system (e.g., sinusitis, otitis, osteomyelitis, and brain abscess). Organisms may gain entrance to the subarachnoid space through compound fractures of the skull and fractures through the nasal sinuses or mastoid or after neurosurgical procedures. Introduction by lumbar puncture is rare. The pathologic background, symptoms, and clinical course of patients with acute purulent meningitis are similar regardless of the causative organisms. The diagnosis and therapy depend on the isolation and identification of the organisms and the determination of the source of the infection.

Acute purulent meningitis may be the result of infection with almost any pathogenic bacteria. Isolated examples of infection by the uncommon forms are recorded in the literature. In the United States, *Streptococcus pneumoniae* now accounts for about one-half of cases when the infecting organism is identified and *Neisseria meningitidis* about one-fourth ([Table 21.1](#)). In recent years, there has been an increase in the incidence of cases in which no organism can be isolated. These patients now comprise the third major category of purulent meningitis. This may be due to the administration of therapy before admission to the hospital and the performance of lumbar puncture. In the neonatal period, *Escherichia coli* and group B streptococci are the most common causative agents. Approximately 60% of the postneonatal bacterial meningitis of children used to be due to *Hemophilus influenzae*. The impact of *H. influenzae* B vaccine has been dramatic. In the past decade there has been a 100-fold decrease in incidence. In 1997 there were less than 300 cases reported. Overall fatality rate from bacterial meningitis is now 10% or less. Many deaths occur during the first 48 hours of hospitalization.

Organism	No. of Cases Reported	Percentage of Total ^a	Incidence ^b	Case Fatality Rate (%) ^c
<i>Hemophilus influenzae</i>	18	7	0.2	6
<i>Streptococcus pneumoniae</i>	117	47	1.1	21
<i>Neisseria meningitidis</i>	62	25	0.6	3
Group B streptococci	31	12	0.3	7
<i>Listeria monocytogenes</i>	20	8	0.2	15

^aBecause of rounding, the percentages do not total 100.

^bThe incidence is the number of cases per 100,000 population.

^cOutcome data were missing for 11 cases of meningitis (5%). The fatality rates are based on cases with known outcome.

From Schubert A, Robinson L, Meyer L, et al., 1997.

TABLE 21.1. CAUSES OF 248 CASES OF BACTERIAL MENINGITIS IN 1995 AND OVERALL FATALITY RATE ACCORDING TO ORGANISM

For convenience, special features of the common forms of acute purulent meningitis are described separately. Neonatal infections are reviewed in [Chapter 74](#).

Meningococcal Meningitis

Meningococcal meningitis was described by Vieusseux in 1805, and the causative organism was identified by Weichselbaum in 1887. It occurs in sporadic form and at irregular intervals in epidemics. Epidemics are especially likely to occur during large shifts in population, as in time of war.

Pathogenesis

Meningococci (*N. meningitidis*) may occasionally gain access to the meninges directly from the nasopharynx through the cribriform plate. The bacteria, however, usually are recovered from blood or cutaneous lesions before the meningitis, thus indicating that spread to the nervous system is hematogenous in most instances. The ventricular fluid may be teeming with organisms before the meninges become inflamed.

Recent studies have defined more clearly the role of bacterial elements in the initiation of meningitis with meningococcus and other bacteria. The bacterial capsule appears most important in the attachment and penetration to gain access to the body. Elements in the bacterial cell wall appear critical in penetration into the cerebrospinal fluid (CSF) space through vascular endothelium and the induction of the inflammatory response.

Pathology

In acute fulminating cases, death may occur before there are any significant pathologic changes in the nervous system. In the usual case, when death does not occur for several days after the onset of the disease, an intense inflammatory reaction occurs in the meninges. The inflammatory reaction is especially severe in the subarachnoid spaces over the convexity of the brain and around the cisterns at the base of the brain. It may extend a short distance along the perivascular spaces into the substance of the brain and spinal cord but rarely breaks into the parenchyma. Meningococci, both intra- and extracellular, are found in the meninges and CSF. With progress of the infection, the pia-arachnoid becomes thickened, and adhesions may form. Adhesions at the base may interfere with the flow of CSF from the fourth ventricle and may produce hydrocephalus. Inflammatory reaction and fibrosis of the meninges along the roots of the cranial nerves are thought to be the cause of the cranial nerve palsies that are seen occasionally. Damage to the auditory nerve often occurs suddenly, and the auditory defect is usually permanent. Such damage may result from extension of the infection to the inner ear or thrombosis of the nutrient artery. Facial paralysis frequently occurs after the meningeal reaction has subsided. Signs and symptoms of parenchymatous damage (e.g., hemiplegia, aphasia, and cerebellar signs) are infrequent and are probably due to infarcts as the result of thrombosis of inflamed arteries or veins.

With effective treatment, and in some cases without treatment, the inflammatory reaction in the meninges subsides, and no evidence of the infection may be found at

autopsy in patients who die months or years later.

In the past, the inflammation in meningitis had been attributed mainly to the toxic effects of the bacteria. In all types of meningitis, the contribution to the inflammatory process of various cytokines released by phagocytic and immunoactive cells, particularly interleukin 1 and tumor necrosis factor, has been recognized. These studies have formed the basis for the use of anti-inflammatory corticosteroids in the treatment of meningitis. Several studies in both *H. influenzae* and *S. pneumoniae* meningitis have suggested an improved outcome with the use of corticosteroids, particularly if the steroids are given shortly before the initiation of antibiotics. Treatment usually continues for 2 to 4 days. The use of corticosteroids in meningitis is still not considered the standard of practice, but many infectious disease specialists advocate it, particularly when clinical signs are severe.

Incidence

Meningococcus is the causative organism in about 25% of all cases of bacterial meningitis in the United States. Serogroup B is now the most commonly reported causative type (50%). Although both the sporadic and the epidemic forms of the disease may attack individuals of all ages, children and young adults are predominantly affected. The normal habitat of the meningococcus is the nasopharynx, and the disease is spread by carriers or by individuals with the disease. A polysaccharide vaccine for groups A, C, Y, and W-B5 meningococci has reduced the incidence of meningococcal infection among military recruits.

Symptoms

The onset of meningococcal meningitis, similar to that of other forms of meningitis, is accompanied by chills and fever, headache, nausea and vomiting, pain in the back, stiffness of the neck, and prostration. The occurrence of herpes labialis, conjunctivitis, and a petechial or hemorrhagic skin rash is common with meningococcal infections. At the onset, the patient is irritable. In children, there is frequently a characteristic sharp shrill cry (meningeal cry). With progress of the disease, the sensorium becomes clouded and stupor or coma may develop. Occasionally, the onset may be fulminant and accompanied by deep coma. Convulsive seizures are often an early symptom, especially in children, but focal neurologic signs are uncommon. Acute fulminating cases with severe circulatory collapse are relatively rare.

Signs

The patient appears acutely ill and may be confused, stuporous, or semicomatose. The temperature is elevated at 101° to 103°F, but it may occasionally be normal at the onset. The pulse is usually rapid and the respiratory rate is increased. Blood pressure is normal except in acute fulminating cases when there may be profound hypotension. A petechial rash may be found in the skin, mucous membranes, or conjunctiva but never in the nail beds. It usually fades in 3 or 4 days. There is rigidity of the neck with positive Kernig and Brudzinski signs. These signs may be absent in newborn, elderly, or comatose patients. Increased intracranial pressure causes bulging of an unclosed anterior fontanelle and periodic respiration. The reflexes are often decreased but occasionally may be increased. Cranial nerve palsies and focal neurologic signs are uncommon and usually do not develop until several days after the onset of the infection. The optic disks are normal, but papilledema may develop if the meningitis persists for more than a week.

Laboratory Data

The blood white cell count is increased, usually in the range of 10,000 to 30,000/mm³, but occasionally may be normal or higher than 40,000/mm³. The urine may contain albumin, casts, and red blood cells. Meningococci can be cultured from the nasopharynx in most cases, from the blood in more than 50% of the cases in the early stages, and from the skin lesions when these are present.

The CSF is under increased pressure, usually between 200 and 500 mm H₂O. The CSF is cloudy (purulent) because it contains a large number of cells, predominantly polymorphonuclear leukocytes. The cell count in the fluid is usually between 2,000 and 10,000/mm³. Occasionally, it may be less than 100 and infrequently more than 20,000/mm³. The protein content is increased. The sugar content is decreased, usually to levels below 20 mg/dL. Gram-negative diplococci can be seen intra- and extracellularly in stained smears of the fluid, and meningococci can be cultured in more than 90% of untreated patients. Particle agglutination may rapidly identify bacterial antigens in the CSF. It cannot be relied on for definite diagnosis, however, because of relatively low specificity and sensitivity. For meningococcus, the capsular polysaccharide is the antigen detected. In unusual instances, the CSF may demonstrate minimal or no increase in cell count and no bacteria on the Gram stain, but *N. meningitidis* may be isolated. Clear CSF in a patient with suspected bacterial meningitis must be cultured carefully.

Complications and Sequelae

The complications and sequelae include those commonly associated with an inflammatory process in the meninges and its blood vessels (i.e., convulsions, cranial nerve palsies, focal cerebral lesions, damage to the spinal cord or nerve roots, hydrocephalus) and those that are due to involvement of other portions of the body by meningococci (e.g., panophthalmitis and other types of ocular infection, arthritis, purpura, pericarditis, endocarditis, myocarditis, pleurisy, orchitis, epididymitis, albuminuria or hematuria, adrenal hemorrhage). Disseminated intravascular coagulation may complicate the meningitis. Complications may also arise from intercurrent infection of the upper respiratory tract, middle ear, and lungs. Any of these complications may leave permanent residua, but the most common sequelae are due to injury of the nervous system. These include deafness, ocular palsies, blindness, changes in mentality, convulsions, and hydrocephalus. With the available methods of treatment, complications and sequelae of the meningeal infection are rare, and the complications due to the involvement of other parts of the body by the meningococci or other intercurrent infections are more readily controlled.

Diagnosis

Meningococcal meningitis can be diagnosed with certainty only by the isolation of the organism from the CSF. The diagnosis can be made, however, with relative certainty before the organisms are isolated in a patient with headache, vomiting, chills and fever, neck stiffness, and a petechial cutaneous rash, especially if there is an epidemic of meningococcal meningitis or if there has been exposure to a known case of meningococcal meningitis.

To establish the diagnosis of meningococcal meningitis, cultures should be made of the skin lesions, nasopharyngeal secretions, blood, and CSF. The diagnosis can be established in many cases by examination of smears of the sediment of the CSF after application of the Gram stain.

Prognosis

The mortality rate of untreated meningococcal meningitis varied widely in different epidemics but was usually between 50% and 90%. With present-day therapy, however, the overall mortality rate is about 10%, and the incidence of complications and sequelae is low.

Features of the disease that influence the mortality rate are the age of the patient, bacteremia, rapidity of treatment, complications, and general condition of the individual. The lowest fatality rates are seen in patients between the ages of 5 and 10. The highest mortality rates occur in infants, in elderly debilitated individuals, and in those with extensive hemorrhages into the adrenal gland.

Treatment

Antibiotic therapy for bacterial meningitis usually commences before the nature of the organism is assured. Therefore, the initial regimen should be appropriate for most likely organisms, the determination of which depends to some extent on the patient's age and the locale. Third-generation cephalosporins, usually ceftriaxone or cefotaxime, have become the first choice of treatment for bacterial meningitis. Their spectrum is broad, and they have become particularly useful since the occurrence of *H. influenzae* and *S. pneumoniae* strains that are resistant to penicillin or ampicillin and amoxicillin. They also require less frequent administration than the penicillins. In circumstances when *S. pneumoniae* resistance to cephalosporins is an issue, vancomycin should be added. If the Gram stain or epidemic setting clearly suggests that meningococcus is the infectious agent, penicillin or ampicillin may be used. Chloramphenicol remains an acceptable choice if allergy to the penicillins and cephalosporins is a problem. Unless a dramatic response to therapy occurs, the CSF should be examined 24 to 48 hours after the initiation of treatment to assess the effectiveness of the medication. Posttreatment examination of the CSF is not a meaningful criterion of recovery, and the CSF does not need to be reexamined if the patient is clinically well.

Dehydration is common, and fluid balance should be monitored carefully to avoid hypovolemic shock. Hyponatremia frequently occurs and may be caused either by

overzealous free water replacement or inappropriate antidiuretic hormone secretion. Heparization should be considered if disseminated intravascular coagulation occurs.

Anticonvulsants should be used to control recurrent seizures. Cerebral edema may require the use of osmotic diuretics or the administration of corticosteroids, but only if early or impending cerebral herniation is evident.

Persons who have had intimate contact with patients with meningococcal meningitis may be given rifampin as a prophylactic measure.

***Hemophilus influenzae* Meningitis**

Infections of the meninges by *H. influenzae* were reported as early as 1899. In the United States and other countries where *H. influenzae* B vaccination is widespread, the incidence of meningitis is now negligible. It remains an important disease elsewhere, however. Where it is still prevalent, *H. influenzae* meningitis is predominantly a disease of infancy and early childhood; more than 50% of the cases occur within the first 2 years of life and 90% before the age of 5. In the United States, *H. influenzae* meningitis is now more common in adults. Serotype B is the most common.

In adults, *H. influenzae* meningitis is more commonly secondary to acute sinusitis, otitis media, or fracture of the skull. It is associated with CSF rhinorrhea, immunologic deficiency, diabetes mellitus, and alcoholism. Currently, cases tend to occur in the autumn and spring, with fewest occurring in the summer months.

The pathology of *H. influenzae* meningitis does not differ from that of other forms of acute purulent meningitis. In patients with a protracted course, localized pockets of infection in the meninges or cortex, internal hydrocephalus, degeneration of cranial nerves, and focal loss of cerebral substance secondary to thrombosis of vessels may be found.

The symptoms and physical signs of *H. influenzae* meningitis are similar to those of other forms of acute bacterial meningitis. The disease usually lasts 10 to 20 days. It may occasionally be fulminating, and frequently it is protracted and extends over several weeks or months.

The CSF changes are similar to those described for the other acute meningitides. The organisms can be cultured from the CSF. Blood cultures are often positive early in the illness.

The mortality rate in untreated cases of *H. influenzae* meningitis in infants is greater than 90%. The prognosis is not so grave in adults, in whom spontaneous recovery is more frequent. Adequate treatment has reduced the mortality rate to about 10%, but sequelae are not uncommon. These include paralysis of extraocular muscles, deafness, blindness, hemiplegia, recurrent convulsions, and mental deficiency. Recent studies have indicated that treatment with anti-inflammatory corticosteroids reduces the frequency of the sequelae, particularly if started just before the initiation of antibiotic treatment.

The diagnosis of *H. influenzae* meningitis is based on the isolation of the organisms from the CSF and blood. *H. influenzae* capsular antigens may be detected in the CSF by particle agglutination, which may rapidly provide information, but is less sensitive and specific than is culture identification.

Because of resistance to ampicillin, third-generation cephalosporins are commonly used in initial therapy of meningitis and are an effective treatment.

Subdural effusion, which may occur in infants with any form of meningitis, is most commonly seen in connection with *H. influenzae* meningitis. Persistent vomiting, bulging fontanelles, convulsion, focal neurologic signs, and persistent fever should lead to consideration of this complication. Prompt relief of the symptoms usually follows evacuation of the effusion by tapping the subdural space through the fontanelles. Persistent or secondary fever without worsening of meningeal signs may be due to an extracranial focus of infection, such as a contaminated urinary or venous catheter, or to drug administration.

Pneumococcal Meningitis

Pneumococcus (*S. pneumoniae*) is about equal in frequency to meningococcus as a cause of meningitis, except that it is more frequent in the elderly population. Meningeal infection is usually a complication of otitis media, mastoiditis, sinusitis, fractures of the skull, upper respiratory infections, and infections of the lung. Alcoholism, asplenic, and sickle cell disease predispose patients to developing pneumococcal meningitis. The infection may occur at any age, but more than 50% of the patients are younger than 1 or older than 50 years of age.

The clinical symptoms, physical signs, and laboratory findings in pneumococcal meningitis are the same as those in other forms of acute purulent meningitis. The diagnosis is usually made without difficulty because the CSF contains many of the organisms. When gram-positive diplococci are seen in smears of the CSF or its sediment, a positive quellung reaction serves to identify both the pneumococcus and its type. Particle agglutination of CSF and serum may be helpful in demonstrating pneumococcal antigen.

Before the introduction of sulfonamides, the mortality rate in pneumococcal meningitis was almost 100%. It is now approximately 20% to 30%. The prognosis for recovery is best in cases that follow fractures of the skull and those with no known source of infection. The mortality rate is especially high when the meningitis follows pneumonia, empyema, or lung abscess or when a persisting bacteremia indicates the presence of an endocarditis. The triad of pneumococcal meningitis, pneumonia, and endocarditis (Austrian syndrome) has a particularly high fatality rate.

The prevalence of penicillin resistant *S. pneumoniae* in the United States has made a third-generation cephalosporin the initial treatment for *S. pneumoniae* until sensitivities are established. Because some strains may also be relatively resistant to the cephalosporins, vancomycin is often used initially as well. The treatment should be continued for 12 to 15 days. Chloramphenicol is an alternative drug for adults who are sensitive to the penicillins and cephalosporins. Any primary focus of infection should be eradicated by surgery if necessary. Persistent CSF fistulas after fractures of the skull must be closed by craniotomy and suturing of the dura. Otherwise, the meningitis will almost certainly recur.

Staphylococcal Meningitis

Staphylococci (*S. aureus* and *S. epidermidis*) are a relatively infrequent cause of meningitis. Meningitis may develop as a result of spread from furuncles on the face or from staphylococcal infections elsewhere in the body. It is sometimes a complication of cavernous sinus thrombosis, epidural or subdural abscess, and neurosurgical procedures involving shunting to relieve hydrocephalus. Endocarditis may be found in association with staphylococcal meningitis. Intravenous treatment with a penicillinase-resistant penicillin (oxacillin) is the preferred treatment. Therapy must be continued for 2 to 4 weeks. In nosocomial infections or other situations in which resistance to oxacillin is likely, treatment with vancomycin is appropriate. Complications, such as ventriculitis, arachnoiditis, and hydrocephalus, may occur. The original focus of infection should be eradicated. Laminectomy should be performed immediately when a spinal epidural abscess is present, and cranial subdural abscess should be drained through craniotomy openings.

Streptococcal Meningitis

Infection with streptococcus accounts for 1% to 2% of all cases of meningitis. Streptococcal meningitis is usually caused by group A organisms. The symptoms are not distinguished from other forms of meningitis. Members of other groups may occasionally be isolated from CSF. It is always secondary to some septic focus, most commonly in the mastoid or nasal sinuses. Treatment is the same as outlined for the treatment of pneumococcal meningitis together with surgical eradication of the primary focus.

Meningitis Caused by Other Bacteria

Meningitis in the newborn infant is most often caused by coliform gram-negative bacilli, especially *E. coli* and group B hemolytic streptococci. It often accompanies septicemia and may show none of the typical signs of meningitis in children and adults. Instead, the infant shows irritability, lethargy, anorexia, and bulging fontanelles. Meningitis caused by gram-negative enteric bacteria also occurs frequently in immunosuppressed or chronically ill hospitalized adult patients and in persons with penetrating head injuries, neurosurgical procedures, congenital defects, or diabetes mellitus. In these circumstances, meningitis may be difficult to

recognize because of altered consciousness related to the underlying illness.

A third-generation cephalosporin and an aminoglycoside are currently used for treatment of gram-negative meningitides. If *Pseudomonas aeruginosa* is present or suspected, ceftazidime is preferred. If initial response is poor, intraventricular administration of the aminoglycoside can be considered. Care also must be taken to ensure that the organism is sensitive to the agents chosen; if not, some other antibiotic should be selected. Gram-negative bacillary meningitis has a high mortality (40% to 70%) and a high morbidity.

Meningitis caused by *Listeria monocytogenes* may occur in adults with chronic diseases (e.g., renal disease with dialysis or transplantation, cancer, connective tissue disorders, chronic alcoholism) and in infants. It may occur, however, without any predisposing factor, and the incidence of such appears to be increasing. Occasionally, *L. monocytogenes* meningitis occurs with prominent brainstem findings (rhombencephalitis). A laboratory report of "diphtheroids" seen on Gram stain or isolated in culture should suggest the possible presence of *L. monocytogenes*. *Listeria* septicemia occurs in about 65% of patients, and the organism may be isolated from blood cultures even when not recoverable from the CSF. The treatment of choice for *L. monocytogenes* meningitis is ampicillin. If *Listeria* is considered a reasonable possibility, ampicillin should be added to initial therapy, because the bacterium is resistant to cephalosporins. High-dose aqueous penicillin and gentamicin is preferred treatment. Trimethoprim/sulfasoxazole is an acceptable alternative. The illness has a mortality rate of 30% to 60%, with the highest fatality rate among elderly patients with malignancies.

Acute Purulent Meningitis of Unknown Cause

Patients may have clinical symptoms indicative of an acute purulent meningitis but with atypical CSF findings. These patients have usually manifested nonspecific symptoms and have often been treated for several days with some form of antimicrobial therapy in dosages sufficient to modify the CSF abnormalities but not sufficient to eradicate the infection. Their symptoms are of longer duration, and the patients have less marked alterations of mental status and die later in their hospitalization than do patients with proven bacterial meningitis. In these cases, the CSF pleocytosis is usually only moderate (500 to 1,000 cells/mm³ with predominance of polymorphonuclear leukocytes), and the sugar content is normal or only slightly decreased. Organisms are not seen on stained smears and are cultured with difficulty. Repeated lumbar puncture may be helpful in arriving at the correct diagnosis. Antibiotics should be selected on the basis of epidemiologic or clinical factors. The age of the patient and the setting in which the infection occurred are the primary considerations. In patients with partially treated meningitis and in those with meningitis of unknown etiology, third-generation cephalosporins and vancomycin are now considered the antibiotics of choice for initial therapy. Ampicillin should be added in neonates or if *L. monocytogenes* is considered. Therapy should be modified if an organism different from that originally suspected is isolated or if the clinical response is less than optimal. The mortality and frequency of neurologic complications of these patients are similar to those of patients in whom the responsible bacteria have been identified.

Recurrent Bacterial Meningitis

Repeated episodes of bacterial meningitis signal a host defect, either in local anatomy or in antibacterial and immunologic defenses. They usually follow trauma; several years may pass between the trauma and the first bout of meningitis. *S. pneumoniae* is the usual pathogen. Bacteria may enter the subarachnoid space through the cribriform plate, a basilar skull fracture, erosive bony changes in the mastoid, congenital dermal defects along the craniospinal axis, penetrating head injuries, or neurosurgical procedures. CSF rhinorrhea or otorrhea is often present but may be transient. It may be detected by testing for a significant concentration of glucose in nasal or aural secretions. Treatment of recurrent meningitis is similar to that for first bouts. Cryptic CSF leaks can be demonstrated by polytomography of the frontal and mastoid regions by monitoring the course of radioiodine-labeled albumin instilled intrathecally or by computed tomography (CT) after intrathecal injection of metrizamide. Patients with recurrent pneumococcal meningitis should be vaccinated with pneumococcal vaccine. Long-term prophylactic treatment with penicillin should be considered. Surgical closure of CSF fistulas is indicated to prevent further episodes of meningitis.

SUBACUTE MENINGITIS

Subacute meningitis is usually due to infection with tubercle bacilli or mycotic organisms. The clinical syndrome differs from that of acute purulent meningitis in that the onset of symptoms is usually less acute, the degree of inflammatory reaction less severe, and the course more prolonged.

Tuberculous Meningitis

Tuberculous meningitis differs from that caused by most other common bacteria in that the course is more prolonged, the mortality rate is higher, the CSF changes are acutely less severe, and treatment is less effective in preventing sequelae.

Pathogenesis

Tuberculous meningitis is always secondary to tuberculosis elsewhere in the body ([Fig. 21.1](#) and [Fig. 21.2](#)). The primary focus of infection is usually in the lungs but may be in the lymph glands, bones, nasal sinuses, gastrointestinal tract, or any organ in the body. The onset of meningeal symptoms may coincide with signs of acute miliary dissemination, or there may be clinical evidence of activity in the primary focus; however, meningitis is often the only manifestation of the disease.

FIG. 21.1. Potts disease (spinal tuberculosis). **A:** T2-weighted sagittal magnetic resonance (MR) scan of the thoracic spine shows abnormally increased signal intensity within four to five consecutive vertebral bodies of the lower thoracic spine. Also evident is a compression fracture of one of the thoracic vertebral bodies with apparent impingement upon the lower thoracic spinal cord. **B and C:** T1-weighted sagittal MR scans of thoracic spine before and after gadolinium enhancement show marked enhancement of affected thoracic vertebral bodies with mild epidural extension, especially at the level of the compression fracture. (Courtesy of Dr. S. Chan.)

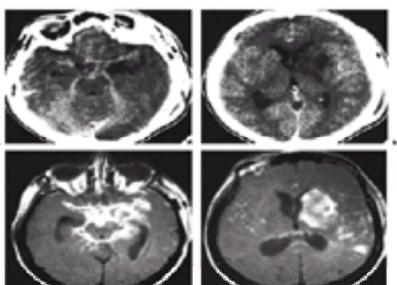

FIG. 21.2. Tuberculous meningitis. **A and B:** Contrast-enhanced axial computed tomographies demonstrate large nonenhancing hypodense lesion in the left temporal lobe (**A**) and left basal ganglia (**B**) most consistent with infarcts. Significant cisternal enhancement is seen consistent with meningitis. **C and D:** T1-weighted axial magnetic resonance scans after gadolinium enhancement show florid contrast enhancement within basal cisterns most consistent with exudative meningitis of

tuberculosis. Enhancement of the left temporal lobe and left basal ganglia lesions suggests persistent inflammation within these infarcts. (Courtesy of Dr. S. Chan.)

Tubercular meningitis usually occurs after the rupture of a meningeal or parenchymal tubercle into the ventricular or subarachnoid space. Tubercles in the nervous system of any appreciable size are rare in the United States, but dissemination may be from minute or microscopic granulomas near the meningeal surfaces. When meningitis is a manifestation of miliary dissemination, it suggests that the meningitis is due to lodgement of bacteria directly in the choroid plexus or meningeal vessels.

Pathology

The meninges over the surface of the brain and the spinal cord are cloudy and thickened, but the process is usually most intense at the base of the brain. A thick collar of fibrosis may form around the optic nerves, cerebral peduncles, and basilar surface of the pons and midbrain. The ventricles are moderately dilated and the ependymal lining is covered with exudate or appears roughened (granular ependymitis). Minute tubercles may be visible in the meninges, choroid plexus, and cerebral parenchyma.

On microscopic examination, the exudate in the thickened meninges is composed chiefly of mononuclear cells, lymphocytes, plasma cells, macrophages, and fibroblasts with an occasional giant cell. The inflammatory process may extend for a short distance into the cerebral substance where microscopic granulomas may also be found. Proliferative changes are frequently seen in the inflamed vessels of the meninges, producing a panarteritis. These arteritic changes may lead to thrombosis of the vessel and cerebral infarcts.

Incidence

Until the 1980s, the incidence of tuberculosis and tubercular meningitis had been declining steadily in the United States because of hygienic improvements and later the development of antibiotic therapy. The incidence, however, is now slowly increasing, in part a result of the propensity of human immunodeficiency virus (HIV)-infected individuals to develop tuberculosis and in part because of the increased immigration from Asian, Latin American, and African countries, which have a high incidence of the disease. Although tuberculous meningitis may occur at any age, it is most common in childhood and early adult life. In areas with a high incidence of tuberculosis, tuberculous meningitis is seen most commonly in infants and young children. In areas of low incidence, such as the United States, tuberculous meningitis is more common in adults. Until recently, adult cases occurred mainly over the age of 40. With the increased incidence of tuberculosis, however, younger adults are again developing the illness.

Symptoms

The onset is usually subacute, with headache, vomiting, fever, bursts of irritability, and nocturnal wakefulness as the most prominent symptoms. Anorexia, loss of weight, and abdominal pain may be present. The prodromal stage lasts for 2 weeks to 3 months in most cases. In young children, a history of close contact with a person known to have tuberculosis is a diagnostic help. Stiffness of the neck and vomiting become evident within a few days. Convulsive seizures are not uncommon in children during the first days of the disease. The headache becomes progressively more severe; there is bulging of the fontanelles in infants. The pain often causes the infant to emit a peculiarly shrill cry (meningeal cry). With progress of the disease, patients become stuporous or comatose. Blindness and signs of damage to other cranial nerves may appear, or there may be convulsive seizures or focal neurologic signs.

Physical Findings

The physical findings in the early stages are those associated with meningeal infection (i.e., fever, irritability, stiffness of the neck, and Kernig and Brudzinski signs). Tendon reflexes may be exaggerated or depressed. Signs of increased intracranial pressure and focal brain damage are rarely present at the onset. The initial irritability is gradually replaced by apathy, confusion, lethargy, and stupor. Papilledema, cranial nerve palsies, and focal neurologic signs are common in the late stages of the disease. There may be external ophthalmoplegia, usually incomplete, unilateral, and involving chiefly the oculomotor nerve. Ophthalmoscopy may demonstrate choroid tubercles. Clinical evidence of tuberculosis elsewhere in the body is usually present. Convulsions, coma, and hemiplegia occur as the disease advances. The temperature, which is only moderately elevated (100° to 102°F) in the early stages, rises to high levels before death. The respiratory and pulse rates are increased. In the terminal stages, respirations become irregular and of the Cheyne-Stokes type.

Diagnosis

The diagnosis of tuberculous meningitis can be established by recovery of the organisms from the CSF. The CSF findings are, however, quite characteristic, and a presumptive diagnosis can be made when the typical abnormalities are present. These include increased pressure; slightly cloudy or ground-glass appearance of the CSF with formation of a clot on standing; moderate pleocytosis of 25 to 500 cells/mm³, with lymphocytes as the predominating cell type; increased protein content; decreased sugar content with values in the range of 20 to 40 mg/dL; a negative serologic test for syphilis or cryptococcal antigen; and absence of growth when the CSF is inoculated on routine culture media. Although none of these abnormalities is diagnostic, their occurrence in combination is usually pathognomonic and is sufficient evidence to warrant intensive therapy until the diagnosis can be confirmed by stained smears of the sediment or pellicle or by culture of the CSF. Smears of the CSF sediment demonstrate acid-fast bacilli in 20% to 30% of patients on single examination; with repeated examinations, the yield of positive smears is increased to 75%. The yield is probably lower in HIV-infected patients, because the illness tends to be more indolent.

Diagnosis is ultimately based on the recovery of the mycobacterium from culture, which may require several weeks. However, detection of mycobacterial DNA in the CSF by polymerase chain reaction (PCR) is highly sensitive and specific and faster. It is not, however, foolproof. Histologic analysis of the CSF sediment is also still useful for detecting the organism and provides the most rapid result.

Other diagnostic aids include a thorough search for a primary focus, including radiographs of the chest and tuberculin skin tests. Patients with tuberculous meningitis may have hyponatremia due to inappropriate secretion of antidiuretic hormone. CT or magnetic resonance imaging (MRI) of the brain in tuberculous meningitis may disclose enhancing exudates in the subarachnoid cisterns, hydrocephalus, areas of infarction, and associated tuberculomas.

Tuberculous meningitis must be differentiated from other forms of acute and subacute meningitis, viral infections, and meningeal reactions to septic foci in the skull or spine.

Acute purulent meningitis is characterized by a high cell count and the presence of the causative organisms in the CSF. Preliminary antibiotic therapy of purulent meningitis may cause the CSF findings to mimic those of tuberculous meningitis.

The CSF in syphilitic meningitis may show changes similar to those of tuberculous meningitis. The normal or relatively normal sugar content and the positive serologic reactions make the diagnosis of syphilitic meningitis relatively easy.

The clinical picture and CSF findings in cryptococcus meningitis may be identical with those of tuberculous meningitis. The differential diagnosis can be made by finding the budding yeast organisms in the counting chamber or in stained smears, by detecting cryptococcal antigen in CSF by the latex agglutination test, and by obtaining a culture of the fungus. Much less frequently, other mycotic infections may involve the meninges.

Meningeal involvement in the course of viral infections, such as mumps, lymphocytic choriomeningitis, or other forms of viral encephalitis, may give a clinical picture similar to that of tuberculous meningitis. In these cases, the CSF sugar content is usually normal or only minimally depressed.

Diffuse involvement of the meninges by metastatic tumors (carcinoma or sarcoma) or by gliogenous tumors may produce meningeal signs. The CSF may contain numerous lymphocytes and polymorphonuclear leukocytes and a reduced sugar content. The triad of mental clarity, lack of fever, and hyporeflexia suggests neoplastic meningitis. A protracted course or the finding of neoplastic cells in the CSF excludes the diagnosis of tuberculous meningitis.

Central nervous system (CNS) sarcoidosis may also cause meningitis with CSF changes similar to those of tuberculous meningitis. Failure to detect microbes by smear or culture and a protracted course are clues to the diagnosis of sarcoidosis. Leptomeningeal biopsy may be needed to establish the diagnosis, but most patients show systemic signs of sarcoidosis in lymph nodes, liver, lung, or muscle (see [Chapter 26](#)).

Prognosis and Course

The natural course of the disease is death in 6 to 8 weeks. With early diagnosis and appropriate treatment, the recovery rate approaches 90%. Delay in diagnosis is associated with rapid progression of neurologic deficits and a poorer prognosis. Prognosis is worst at the extremes of life, particularly in the elderly person. The presence of cranial nerve abnormalities on admission, confusion, lethargy, and elevated CSF protein concentration are associated with a poor prognosis. The presence of active tuberculosis in other organs or of miliary tuberculosis does not significantly affect the prognosis if antitubercular therapy is given. Relapses occasionally occur after months or even years in apparently cured patients.

Sequelae

Minor or major sequelae occur in about 25% of the patients who recover. These vary from minimal degree of facial weakness to severe intellectual and physical disorganization. Physical defects include deafness, convulsive seizures, blindness, hemiplegia, paraplegia, and quadriplegia. Intracranial calcifications may appear 2 to 3 years after the onset of the disease.

Treatment

Treatment should be started immediately without waiting for bacteriologic confirmation of the diagnosis in a patient with the characteristic clinical symptoms and CSF findings. It is generally agreed that the prognosis for recovery and freedom from sequelae are directly related to the promptness of the initiation of therapy. Concomitant with the resurgence of tuberculosis in the United States has been the emergence of multidrug-resistant organisms. Treatment is now commonly started with four drugs, usually isoniazid, rifampin, pyrazinamide, and ethambutol; streptomycin is an alternative if one of the preferred antibiotics cannot be used. Other second-line drugs may be substituted if absolutely necessary. The regimen later can be modified and the number of agents reduced if the sensitivities of the isolated bacterium allow. Treatment is usually for 18 to 24 months. Corticosteroids may prove beneficial in the early phases of the disease when there is evidence of subarachnoid block or impending cerebral herniation. Peripheral neuropathy secondary to isoniazid treatment can be prevented by giving pyridoxine. Intrathecal therapy is not indicated.

In association with the HIV epidemic has been an increased incidence of infection with nontubercular mycobacteria, particularly of the avium-intracellulare group. Although these organisms are occasionally isolated from the CSF, the meningeal reaction related to their presence is a mild and indolent process. Treatment of the infections is difficult.

SUBDURAL AND EPIDURAL INFECTIONS

Cerebral Subdural Empyema

A collection of pus between the inner surface of the dura and the outer surface of the arachnoid of the brain is known as *subdural empyema*.

Etiology

Subdural empyema may result from the direct extension of infection from the middle ear, the nasal sinuses, or the meninges. It may develop as a complication of compound fractures of the skull or in the course of septicemia. An acute attack of sinusitis just before the development of subdural empyema is common. The mechanism of the formation of subdural empyema after compound fractures of the skull is easily understood, but the factors that lead to subdural infection rather than leptomeningitis or cerebral abscess in patients with infections of the nasal sinuses or mastoids are less clear. Chronic infection of the mastoid or paranasal sinuses with thrombophlebitis of the venous sinuses or osteomyelitis and necrosis of the cranial vault commonly precedes the development of the subdural infection.

The infection is most often due to streptococcus. Other bacteria frequently recovered from subdural pus are staphylococci and gram-negative enteric organisms.

Pathology

The pathologic findings depend on the mode of entry of the infection into the subdural space. In traumatic cases, there may be osteomyelitis of the overlying skull, with or without accompanying foreign bodies. When the abscess is secondary to infection of the nasal sinuses or middle ear, thrombophlebitis of the venous sinuses or osteomyelitis of the frontal or temporal bone is a common finding. Dorsolateral and interhemispheric collections of pus are common; collections beneath the cerebral hemispheres are uncommon. After paranasal infections, subdural pus forms at the frontal poles and extends posteriorly over the convexity of the frontal lobe. After ear infection, the subdural pus passes posteriorly and medially over the falx to the tentorium and occipital poles. The brain beneath the pus is molded in a manner similar to that seen in cases of subdural hematoma. Thrombosis or thrombophlebitis of the superficial cortical veins, especially in the frontal region, is common and produces a hemorrhagic softening of the gray and white matter drained by the thrombosed vessels. The subarachnoid spaces beneath the subdural empyema are filled with a purulent exudate, but there is no generalized leptomeningitis in the initial stage.

Incidence

Subdural empyema is a relatively rare form of intracranial infection, occurring less than half as frequently as brain abscess. It may develop at any age but is most common in children and young adults. Males are more frequently affected than females.

Symptoms and Signs

Symptoms include those associated with the focus or origin of the infection and those due to the intracranial extension. Local pain and tenderness are present in the region of the infected nasal sinus or ear. Orbital swelling is usually present when the infection is secondary to frontal sinus disease. Chills, fever, and severe headache are common initial symptoms of the intracranial involvement. Neck stiffness and Kernig sign are present. With progress of the infection, the patient lapses into a confused, somnolent, or comatose state. Thrombophlebitis of the cortical veins is manifested by jacksonian or generalized convulsions and by the appearance of focal neurologic signs (e.g., hemiplegia, aphasia, paralysis of conjugate deviation of the eyes, cortical sensory loss). In the late stages, the intracranial pressure is increased and papilledema may occur. The entire clinical picture may evolve in as little as a few hours or as long as 10 days.

Laboratory Data

A marked peripheral leukocytosis is usually present. Radiographs of the skull may show evidence of infection of the mastoid or nasal sinuses or of osteomyelitis of the skull. The CSF is under increased pressure. It is usually clear and colorless, and there is a moderate pleocytosis, varying from 25 to 500 cells/mm³ with 10% to 80% polymorphonuclear leukocytes. In some patients, the CSF cellular response may be composed chiefly of lymphocytes or mononuclear cells. CSF pleocytosis may be absent. The protein content is increased, with values commonly in the range of 75 to 150 mg/dL. The sugar content is normal, and the CSF is sterile unless the subdural infection is secondary to a purulent leptomeningitis. Spinal puncture should be done with caution because instances of transtentorial herniation within 8 hours after lumbar puncture have been described in this condition. Lumbar puncture should be avoided if the diagnosis can be established in other ways.

CT of the head characteristically demonstrates a crescent-shaped area of hypodensity at the periphery of the brain and mass displacement of the cerebral ventricles and midline structures. There usually is contrast enhancement between the empyema and cerebral cortex. CT may fail to define the pus collection in some patients with typical clinical presentations, however. MRI appears to be more sensitive. Arteriography is no longer required.

Diagnosis

The diagnosis of subdural empyema should be considered whenever meningeal symptoms or focal neurologic signs develop in patients presenting evidence of a suppurative process in nasal sinuses, mastoid process, or other cranial structures.

Subdural empyema must be differentiated from other intracranial complications of infections in the ear or nasal sinus. These include extradural abscess, sinus thrombosis, and brain abscess. The presence of focal neurologic signs and neck stiffness is against the diagnosis of epidural abscess.

The differential diagnosis between subdural empyema and septic thrombosis of the superior longitudinal sinus is difficult because focal neurologic signs and convulsive seizures are common to both conditions. In fact, thrombosis of the sinus or its tributaries is a frequent complication of subdural empyema. Factors in favor of the diagnosis of sinus thrombosis are a septic temperature and the absence of signs of meningeal irritation. Subdural empyema can also be confused with viral encephalitis or various types of meningitis. The diagnosis may be obscured by early antibiotic therapy. Brain abscess can be distinguished by the relatively insidious onset and the protracted course.

Clinical Course

The mortality rate is high (25% to 40%) because of failure to make an early diagnosis. If the disorder is untreated, death commonly follows the onset of focal neurologic signs within 6 days. Uncontrollable cerebral edema contributes to a lethal outcome. The causes of death are dural venous sinus thrombosis, fulminant meningitis, and multiple intracerebral abscesses. With prompt evacuation of the pus and chemotherapy, recovery is possible even after focal neurologic signs have appeared. Gradual improvement of the focal neurologic signs may occur after recovery from the infection. Seizures, hemiparesis, and other focal deficits may be long-term sequelae, however.

Treatment

The treatment of subdural empyema is prompt surgical evacuation of the pus through trephine operation, carefully avoiding passage through the infected nasal sinuses. Systemic antibiotic therapy should commence before surgery and should be tailored to any suspected organism. If *S. aureus* is suspected, penicillin G and metronidazole with vancomycin are suitable as a broad-spectrum treatment before culture reports. Sometimes a third-generation cephalosporin also is added. Treatment is usually 3 to 4 weeks. Instillation of antibiotics into the subdural space during surgery is of uncertain efficacy but commonly is done. Treatment of cerebral edema is also a necessity.

Intracranial Epidural Abscess

Abscesses confined to the epidural space are frequent and are almost always associated with overlying infection in the cranial bones. Penetration from chronic sinusitis or mastoiditis is most common, but infection after head trauma or neurosurgery may also cause this problem. Occasionally, no source is apparent. Frequently, intracranial epidural abscess is associated with deeper penetration of the infection and subdural empyema, meningitis, or intraparenchymal abscess. Severe headache, fever, malaise, and findings referable to the initial site of infection are the features of isolated intracranial epidural abscess. Focal neurologic findings are rarely present. Diagnosis is made most conveniently by CT or MRI, which usually demonstrate a characteristic extradural defect ([Fig. 21.3](#)). MRI appears to be more sensitive when the lesion is small. If no abnormality is detected, repeat scanning should be performed when headache persists after antibiotic treatment of an infected sinus or other focus. Evaluation of CSF is not of great help. The protein may be modestly elevated and a mild pleocytosis may be present, but organisms are not seen on Gram stain and cultures are routinely negative. Lumbar puncture is certainly discouraged until after scanning has established that significant mass effect is not present. As with most abscesses, surgical drainage is usually necessary to ensure cure. If, however, the scan and lack of neurologic findings suggest that the infection is confined to the epidural space, trephination may suffice and a craniotomy can be avoided. Appropriate antibiotic treatment is the same as that for subdural empyema, because the sources of infection are similar. It is not clear whether irrigation of the epidural space with antibiotic is useful.

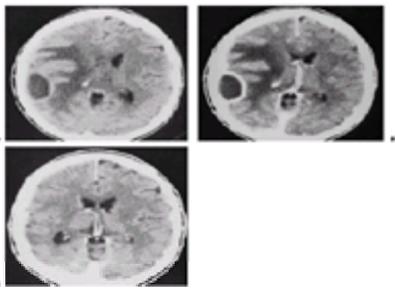

FIG. 21.3. Epidural abscess. **A:** An axial noncontrast computed tomography demonstrates a right posterior temporal lucent epidural collection with prominent white matter edema in the underlying cerebral parenchyma. Calcified choroid in the effaced atrium of the right lateral ventricle is shifted anteromedially. **B:** Postcontrast scan at this same level demonstrates abnormal dural enhancement and shift of the internal cerebral veins due to the mass effect. **C:** A contrast-enhanced scan after surgical drainage demonstrates resolution of the abscess, edema, mass effect, and shift. (Courtesy of Drs. J. A. Bello and S. K. Hilal.)

Spinal Epidural Abscess

Spinal epidural abscess is a collection of purulent material located outside the dura mater within the spinal canal. Infections of the spinal epidural space are accompanied by fever, headache, pain in the back, weakness of the lower extremities, and, finally, complete paraplegia.

Etiology

Infections may reach the fatty tissue in the spinal epidural space by one of three routes: direct extension from inflammatory processes in adjacent tissues, such as decubitus ulcers, carbuncles, or perinephric abscesses; metastasis through the blood from infections elsewhere in the body; and perforating wounds, spinal surgery, or lumbar puncture. The first route of infection accounts for most cases. The primary site of infection is often a furuncle on the skin, but septic foci in the tonsils, teeth, lungs, uterus, or other organ may metastasize to the epidural fat. Chronic debilitating diseases, diabetes mellitus, immunosuppressive therapy, and heroin abuse are contributing factors.

S. aureus accounts for 50% to 60% of epidural abscesses. Other bacteria responsible include *E. coli*, other gram-negative organisms, and hemolytic and anaerobic streptococci.

Pathology

No region of the spine is immune to infection, but the midthoracic vertebrae are most frequently affected. The character of the osteomyelitis in the vertebra is similar to that encountered in other bones of the body. The laminae are most commonly involved, but any part of the vertebra, including the body, may be the seat of the infection. The infection in the epidural space may be acute or chronic.

In acute cases, which are by far the most common, a purulent necrosis of the epidural fat extends over several segments of the entire length of the cord. The pus is usually posterior to the spinal cord but may be on the anterior surface. When the infecting organism is of low virulence, the infection may localize and assume a granulomatous nature.

The lesions in the spinal cord depend on the extent to which the infection has progressed before treatment is begun. Necrosis in the periphery of the cord may result

from pressure of the abscess, or myelomalacia of one or several segments may occur when the veins or arteries are thrombosed. There is ascending degeneration above and descending degeneration below the level of the necrotic lesion. The substance of the spinal cord occasionally may be infected by extension through the meninges, with the formation of a spinal cord abscess.

Incidence

Spinal epidural abscesses account for approximately 1 of every 20,000 admissions to hospitals in the United States. They can occur at all ages; 60% affect adults between 20 and 50 years of age.

Symptoms and Signs

The symptoms of acute spinal epidural abscess develop suddenly, several days or weeks after an infection of the skin or other parts of the body. The preceding infection occasionally may be so slight that it is overlooked. Severe back pain is usually the presenting symptom. Malaise, fever, neck stiffness, and headache may be present or follow in a few days. Usually within hours, but sometimes not for several weeks, initial symptoms are followed by radicular pain. If the abscess is untreated, muscular weakness and paralysis of the legs may develop suddenly.

Fever and malaise are usually present in the early phase; lethargy or irritability develops as the disease progresses. There is neck stiffness and a Kernig sign. Local percussion tenderness over the spine is an important diagnostic sign. Tendon reflexes may be increased or decreased, and the plantar responses may be extensor. With thrombosis of the spinal vessels, a flaccid paraplegia occurs with complete loss of sensation below the level of the lesion and paralysis of the bladder or rectum. Immediately after the onset of paraplegia, tendon reflexes are absent in the paralyzed extremities. There is often erythema and swelling in the area of back pain.

In chronic cases in which the infection is localized and there is granuloma formation, the neurologic signs are similar to those seen with other types of extradural tumors. Fever is rare; weakness and paralysis may not develop for weeks or months.

Laboratory Data

In acute cases, leukocytosis is present in the blood. The erythrocyte sedimentation rate is usually elevated. Radiographs of the spine are usually normal but may show osteomyelitis or a contiguous abscess ([Fig. 21.4](#)).

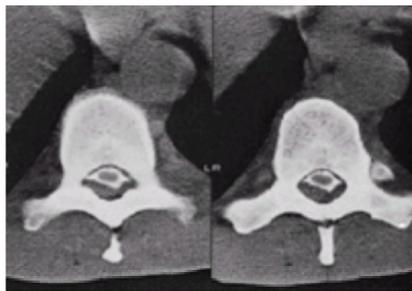

FIG. 21.4. Epidural abscess. Axial computed tomography myelography demonstrates abnormal epidural soft-tissue density posterior to and deforming the thecal sac, with anterior displacement of the cord at this lower thoracic level. (Courtesy of Dr. S. K. Hilal.)

Myelography is almost invariably abnormal. Complete extradural block is found in 80% of patients; the others demonstrate partial block. It is critically important to consider the possibility of epidural abscess in any case of acute or subacute myelopathy, because lumbar puncture may penetrate the pus and carry infection into the subarachnoid space. When complete block or a lower thoracic-lumbar abscess is suspected, myelography should be performed by cervical puncture. The needle should be advanced slowly and suction applied with a syringe as the epidural space is approached. If the abscess has extended to the level of the puncture, pus may be withdrawn for culture and the procedure terminated.

Epidural abscesses can be demonstrated by spinal CT, with or without use of intravenous contrast material. MRI, especially with gadolinium enhancement, is even more sensitive ([Fig. 21.5](#)). When lesions are clearly defined by either of these techniques, myelography is not necessary.

FIG. 21.5. Epidural abscess. **A and B:** T1-weighted and T2-weighted sagittal magnetic resonance (MR) scans demonstrate a vague area of mixed signal intensity within the anterior epidural space extending from the top of the L5 vertebral level down to the S1 level, suggestive of an underlying epidural process. Also noted is mild increased signal intensity within the L5 and S1 vertebral bodies on the T2-weighted images suggestive of adjacent vertebral inflammation or degeneration. (Degenerative disc disease is present at the L4-L5 disc space.) **C and D:** T1-weighted sagittal and axial MR scans demonstrate significant contrast enhancement within the anterior epidural space between L5 and S1 levels, consistent with epidural infection. Axial view shows compression upon spinal sac anteriorly. Patient had known *Staphylococcus aureus* sepsis; epidural abscess receded with intravenous antibiotics. (Courtesy of Dr. S. Chan.)

CSF pressure is normal or increased and there is complete or almost complete subarachnoid block. The CSF is xanthochromic or cloudy in appearance. There is usually a slight or moderate pleocytosis in the CSF, varying from a few to several hundred cells per cubic millimeter. Rarely, no cells may be present. The protein content is increased with values commonly between 100 and 1,500 mg/dL. The CSF sugar content is normal, and CSF cultures are sterile unless meningitis has developed.

Diagnosis

A presumptive diagnosis can be made when subarachnoid block is found in a patient with back and leg pain of acute onset with back tenderness and signs of meningeal irritation. This is true when there is a history of recent pyogenic infection. The diagnosis should be made before signs of transection of the cord develop.

Acute spinal epidural abscess must be differentiated from acute or subacute meningitis, acute poliomyelitis, infectious polyneuritis, acute transverse myelitis, multiple sclerosis, and epidural hematoma. The clinical, CSF, and myelography findings are sufficient to differentiate these conditions. Chronic epidural abscess may be

confused with chronic adhesive arachnoiditis or tumors in the epidural space.

The diagnosis of granulomatous infection is rarely made before operation. The signs are those of chronic cord compression. Operation is indicated by the presence of these signs and evidence of spinal subarachnoid block.

Course and Prognosis

If treatment is delayed in acute spinal epidural abscess, complete or incomplete transection syndrome almost invariably develops. Flaccid paraplegia, sphincter paralysis, and sensory loss below the level of the lesion persist throughout the life of the individual.

The mortality rate is approximately 30% in the acute cases and 10% in the chronic cases. Death may occur in acute cases as a direct result of the infection or secondary to complications. Total recovery may occur in patients who do not have total paralysis or who have weakness lasting less than 36 hours. Of patients paralyzed for 48 hours or more, 50% progress to permanent paralysis and death.

Treatment

The treatment of spinal epidural abscess is prompt surgical drainage by laminectomy. Antibiotics should be administered before and after the operation. Aerobic and anaerobic cultures should be obtained at operation. The area of suppuration should be irrigated with an antibiotic solution. Delay in draining the abscess may result in permanent paralysis. Little improvement can be expected in acute cases with signs of transection if the operation is performed after they occur because these signs are caused by softening of the spinal cord secondary to thrombosis of the spinal vessels. In chronic cases where compression of the cord plays a role in the production of the signs, considerable improvement in the neurologic symptoms and signs may be expected after the operation.

When there is back pain with minimal or no neurologic abnormality, surgery may not be needed, but epidural aspiration for culture is used to guide antibiotic therapy, followed by MRI monitoring of the course. This is potentially perilous because progression of neurologic dysfunction can be rapid and irreversible. Close observation and immediate surgical drainage are necessary if neurologic deterioration occurs.

Infective Endocarditis

The etiologic causes of infective endocarditis have changed remarkably in the antibiotic era. Rheumatic heart disease now accounts for fewer than 25% of cases, whereas it once accounted for nearly 75%. Endocarditis secondary to prosthetic valves or other intravascular devices, intravenous drug addiction, and degenerative cardiac disease related to aging has become more prominent. Congenital heart abnormalities remain an important cause, especially in children. Unfortunately, morbidity and mortality rates have not been affected much by these etiologic changes and the use of antibiotics, thus probably reflecting more severe infections associated with these newer causes. In the past, the terms acute or subacute were used to describe infective endocarditis. These subdivisions, however, are artificial; the underlying cause of the endocarditis and the specific organism involved are more useful considerations when determining prognosis and treatment.

Neurologic complications of infective endocarditis are important because of their frequency and severity. They may be the first manifestation of the underlying intracardiac infection. Cerebral infarcts, either bland or less often hemorrhagic, are most common. Infarcts of cranial or peripheral nerves and of the spinal cord rarely occur. Intracranial hemorrhage caused by mycotic aneurysms, brain abscess, and meningitis also are frequent. These complications presumably result from emboli of infective material from the heart. Inflammatory arteritis also has been implicated as a cause, particularly of intracranial hemorrhage when no mycotic aneurysm is apparent. An encephalopathy sometimes with prominent psychiatric features can occur and may be related to microemboli with or without microabscess formation, vasculitis, toxic effects of medications, or metabolic derangements associated with the illness occurring either individually or concurrently. Seizures may occur in association with any of the cerebral complications.

Infective endocarditis always should be considered in sudden neurologic vascular events, particularly when known predisposing factors exist, such as cardiac disease, drug addiction, fever, or infection elsewhere in the body. The frequency of neurologic events is between 20% and 40% in most reported series of endocarditis. They appear to occur more frequently in the elderly patient. As might be anticipated, neurologic complications are more frequent in endocarditis that affects the left side of the heart. Right-sided lesions usually cause meningitis, intracerebral abscesses, or encephalopathy rather than embolic-related events, although these still rarely occur. The type of organism is also important in determining the frequency of neurologic events. *S. aureus* and *S. pneumoniae* in particular are associated with a high risk of nervous system complications.

Diagnostic evaluation of neurologic events depends in part on whether the presence of infective endocarditis already has been established. Imaging studies are important to define the nature of lesions that have focal neurologic findings. Differentiation of infarcts from hemorrhages or abscesses may be accomplished by either CT or MRI. On occasion, both techniques may be necessary to define clearly the nature of the lesion. Analysis of the CSF is mandatory in cases of meningitis regardless of whether the diagnosis of infective endocarditis already has been made. Such analysis also is useful in encephalopathic conditions to evaluate for low-grade meningitic infection. Lumbar puncture also should be considered strongly in stroke associated with fever even if endocarditis is not yet documented. It is probably not useful in known infective endocarditis with focal CNS presentations and a clearly defined lesion with imaging studies. Demonstration of suspected mycotic aneurysms can be made by arteriography. The usefulness of magnetic resonance angiography has not been established yet. Some practitioners have advocated arteriography in all cases of infective endocarditis. No controlled studies have been done to determine the indications for arteriography, and indications for surgical treatment of detected aneurysms also are uncertain.

Treatment of infective endocarditis with nervous system complications is primarily treatment of the cardiac lesion. Prolonged antibiotic treatment is required, and surgical replacement of infected valves may be appropriate. In most instances, treatment of nervous system events is nonspecific and supportive. Brain abscesses that do not resolve rapidly with systemic antibiotics should be drained. As noted, indications for surgical management of mycotic aneurysms is uncertain and must be decided on an individual basis. The aneurysms usually do not have a neck and cannot be conveniently clipped. Sacrifice of the distal vessel usually is necessary, and further cerebral damage is possible.

Leprosy

Leprosy (Hansen disease) is a chronic disease due to infection by *Mycobacterium leprae*, which has a predilection for the skin and the peripheral nerves. The bacillus has this predilection for mucous membranes and skin, including superficial nerves, because these are the cooler areas of the body where the temperature is ideal for multiplication. Two major clinical types are recognized: lepromatous and tuberculoid. The type that predominates appears to depend on the nature of the immunologic response to the organism.

Etiology

M. leprae is an acid-fast rod-shaped organism morphologically similar to the tubercle bacillus. The organism can be demonstrated in the cutaneous lesion and is sometimes present in the blood of lepromatous patients. The disease is transmitted by direct contact, which must be intimate and prolonged because the contagiousness is low. The portal of entry is probably through abrasions in the skin or mucous membranes of the upper respiratory tract. The incubation period is long, averaging 3 to 4 years in children and longer in adults. Transmission from patients with tuberculoid leprosy is rare.

Pathology

The affected nerve trunks are diffusely thickened or are studded with nodular swellings. There is an overgrowth of connective tissue with degeneration of the axon and myelin sheath. Bacilli are present in the perineurium and endoneurial septa. They also have been found in dorsal root ganglia, spinal cord, and brain, but they do not produce any significant lesions within the CNS. Degenerative changes in the posterior funiculi of the cord, which are found in some cases, can be attributed to the peripheral neuritis.

Incidence

Leprosy is most common in tropical and subtropical climates, and it is estimated that 10 to 20 million people are infected. The disease is prevalent in South and

Central America, China, India, and Africa. It is uncommon in Europe or North America. In the United States, the disease is mostly confined to Louisiana, Texas, Florida, Southern California, Hawaii, and New York. The number of new cases in the United States has increased in recent years because of immigration from endemic areas.

Children are especially susceptible to the disease, but it may occur in adults. In childhood, the disease is evenly distributed between the two sexes, but among adults, men are more frequently affected than women.

Symptoms and Signs

In most cases, a mixture of cutaneous and peripheral nerve lesions occurs. Neurologic involvement is more frequent and occurs early in the tuberculoid form. The earliest manifestation of neural leprosy is an erythematous macule, the lepride. This lesion grows by peripheral extension to form an annular macule. The macule has an atrophic depigmented center that is partially or completely anesthetic. These lesions may attain an enormous size and cover the major portion of one extremity or the torso. Infection of the nerve may result in the formation of nodules or fusiform swelling along its course. Although any of the peripheral nerves may be affected, the disease has a predilection for the ulnar, great auricular, posterior tibial, common peroneal, and the Vth and VIIth cranial nerves. These nerves are involved at locations where their course is superficial. Repeated attacks of neuralgic pains often precede the onset of weakness or sensory loss.

Cranial Nerves

Involvement of the Vth cranial nerve is evident by the appearance of patches of anesthesia on the face. Involvement of the entire sensory distribution of the nerve or its motor division is rare. Keratitis, ulceration, and blindness may ensue as results of injury to the anesthetic cornea. Complete paralysis of the facial nerve is rare, but weakness of a portion of one or several muscles is common. The muscles of the upper half of the face are most severely affected. Partial paralysis of the orbicularis and other facial muscles may result in lagophthalmos, ectropion, and facial asymmetry. Involvement of the oculomotor or other cranial nerves is rare.

Motor System

Weakness and atrophy develop in the muscles innervated by the affected nerves. There is wasting of the small muscles of the hands and feet, with later extension to the forearm and leg, but the proximal muscles usually are spared. Clawing of the hands or feet is common, but wrist drop and foot drop are late manifestations. Fasciculations may occur and contractures may develop.

Sensory System

Cutaneous sensation is impaired or lost in the distribution of the affected nerves in a somewhat irregular or patchy fashion. Various types of dissociated sensory impairment are seen. The sensory impairment may be of a nerve or root distribution but more commonly it is of a glove-and-stocking type. Deep sensation, pressure pain, the appreciation of vibration, and position sense usually are spared or are affected less severely than is superficial cutaneous sensation.

Reflexes

Tendon reflexes are usually preserved until late advanced stages of nerve damage when they are reduced or lost. The abdominal skin reflexes and plantar responses are normal.

Other Signs

Vasomotor and trophic disturbances are usually present. Anhydrosis and cyanosis of the hands and feet are common. Trophic ulcers develop on the knuckles and on the plantar surface of the feet. There may be various arthropathies and resorption of the bones of the fingers, starting in the terminal phalanges and progressing upward. The skin shrinks as digits become shorter, and finally the nail may be attached to a small stump.

Laboratory Data

There are no diagnostic changes in the blood, although mild anemia and an increased erythrocyte sedimentation rate may be seen. As many as 33% of lepromatous patients have false-positive serologic tests for syphilis. The only CSF abnormality is a slight increase in the protein content.

Diagnosis

The diagnosis of leprosy is made without difficulty from the characteristic skin and neuritis lesions. The clinical picture occasionally may have a superficial similarity to that of syringomyelia, hypertrophic interstitial neuritis, or von Recklinghausen disease. The correct diagnosis usually is not difficult if the possibility of leprosy is kept in mind and scrapings from cutaneous lesions and nerve biopsy specimens are examined for acid-fast bacilli.

Course and Prognosis

The prognosis in the neural form (primarily tuberculoid) of the disease is less grave than that in the cutaneous form (primarily lepromatous), in which death within 10 to 20 years is the rule. Neural leprosy is not necessarily fatal. The progress of the neuritis is slow, and the disease may come to a spontaneous arrest or may be controlled by therapy. Incapacitation may result from the paralyses and disfigurement.

Treatment

Dapsone (4,4-diamino-diphenylsulphone), a folate antagonist, is the primary drug for treatment, supplemented by a single dose of rifampin once a month for the tuberculoid form. Treatment continues for at least 6 months. For the lepromatous form, dapsone and rifampin are supplemented with clofazimine, and treatment continues for at least 2 years.

RICKETTSIAL INFECTIONS

Rickettsiae are obligate intracellular parasites about the size of bacteria. They are visible in microscopic preparations as pleomorphic coccobacilli. Each rickettsiae pathogenic for humans is capable of multiplying in arthropods and in animals and humans. They have a gram-negative-like cell wall and an internal structure similar to that of bacteria (i.e., with a prokaryotic DNA arrangement and ribosomes). Diseases due to rickettsiae are divided into five groups on the basis of their biologic properties and epidemiologic features: typhus, spotted fever, scrub typhus, Q fever, and trench fever. Invasion of the nervous system is common only in infections with organisms of the first three groups. Infection with Rocky Mountain spotted fever is the most important rickettsial infection currently in the United States. A sixth group of rickettsiae in the genus *Ehrlichia* have come to be recognized as significant pathogens in humans in the past 10 years. Ehrlichial infections have also been associated with CNS symptoms, but the frequency of nervous system infection is still not certain.

Rocky Mountain Spotted Fever

Rocky Mountain spotted fever is an acute endemic febrile disease produced by infection with the *Rickettsia rickettsi*. It is transmitted to humans by various ticks, the most common of which are the *Dermacentor andersoni* (wood tick) in the Rocky Mountain and Pacific Coast states and the *Dermacentor variabilis* (dog tick) in the East and South. Rabbits, squirrels, and other small rodents serve as hosts for the ticks and are responsible for maintaining the infection in nature. Diseases of the Rocky Mountain spotted fever group are present throughout the world.

Pathology

The pathologic changes are most severe in the skin, but the heart, lungs, and CNS also are involved. The brain is edematous, and minute petechial hemorrhages are

present. The characteristic microscopic lesions are small round nodules composed of elongated microglia, lymphocytes, and endothelial cells. These are scattered diffusely through the nervous system in close relation to small vessels. Vessels in the center of the lesions show severe degeneration. The endothelial cells are swollen, and the lumen may be occluded. Minute areas of focal necrosis are common as the result of thrombosis of small arterioles. Some degree of perivascular infiltration without the presence of nodules may be seen in both the meninges and the brain parenchyma.

Incidence

The disease has been reported from almost all states and from Canada, Mexico, and South America. Approximately 1,000 cases are reported annually in the United States, mostly from rural areas. Most cases are seen during the period of maximal tick activity—the late spring and early summer months.

Symptoms and Signs

A history of tick bite is elicited in 80% of affected patients. The incubation period varies from 3 to 12 days. The onset is usually abrupt, with severe headache, fever, chills, myalgias, arthralgias, restlessness, prostration, and, at times, delirium and coma. A rose-red maculopapular rash appears between the second and sixth day (usually on the fourth febrile day) on the wrists, ankles, palms, soles, and forearms. The rash rapidly spreads to the legs, arms, and chest. The rash becomes petechial and fails to fade on pressure by about the fourth day.

Neurologic symptoms occur early and are frequently a prominent feature. Headache, restlessness, insomnia, and back stiffness are common. Delirium or coma alternating with restlessness is present during the height of the fever. Tremors, athetoid movements, convulsions, opisthotonos, and muscular rigidity may occur. Retinal venous engorgement, retinal edema, papilledema, retinal exudates, and choroiditis may occur. Deafness, visual disturbances, slurred speech, and mental confusion may be present and may persist for a few weeks following recovery.

Laboratory Data

The white cell count is either normal or mildly elevated. Proteinuria, hematuria, and oliguria commonly occur. CSF pressure and glucose are usually normal. The CSF is clear, but a slight lymphocytic pleocytosis and protein elevation may occur. Eosinophilic meningitis has been reported.

Diagnosis

The diagnosis is made on the basis of the development of the characteristic rash and other symptoms of the disease after exposure to ticks. Clinical distinction from typhus fever may be impossible. The onset of the rash in distal parts of the limbs favors a diagnosis of Rocky Mountain spotted fever. In rare instances, however, neurologic signs may occur before the rash appears. A rise in antibody titer during the second week of illness can be detected by specific complement fixation, immunofluorescence and microagglutination tests, or by the Weil-Felix reaction with *Proteus* OX-19 and OX-2.

Course and Prognosis

In patients who recover, the fever falls at about the end of the third week, although mild cases may become afebrile before the end of the second week. Convalescence may be slow, and residuals of damage to the nervous system may persist for several months.

In untreated cases, the overall case fatality is about 20%. Prognosis depends on the severity of the infection, host factors (e.g., age, the presence of other illness), and the promptness with which antimicrobial treatment is started.

Treatment

Control measures include personal care and vaccination. Tick-infested areas should be avoided. If exposure is necessary, high boots, leggings, or socks should be worn outside the trouser legs. Body and clothing should be inspected after exposure, and attached ticks should be removed with tweezers. The hands should be carefully washed after handling the ticks. Workers whose occupations require constant exposure to tick-infested regions should be vaccinated yearly, just before the advent of the tick season.

The treatment of Rocky Mountain spotted fever is the prompt administration of tetracycline or doxycycline. In children, chloramphenicol is preferred to avoid tooth discoloration. Any patient seriously considered to have Rocky Mountain spotted fever should be treated promptly while diagnostic tests proceed.

The other rickettsial infections that may affect the nervous system directly either are rare or do not occur in the United States. Except for some variation in their incubation times, the pathology and clinical picture are similar to those of Rocky Mountain spotted fever and need not be described again. All such infections respond to tetracyclines or chloramphenicol.

Typhus Fever

Three types of infection with rickettsiae of the typhus group are recognized: primary louse-borne epidemic typhus; its recrudescence form, Brill-Zinsser disease; and flea-borne endemic murine typhus.

Incidence

Since its recognition in the 16th century, typhus has been known as one of the great epidemic diseases of the world. It is especially prevalent in war times or whenever there is a massing of people in camps, prisons, or ships.

Epidemic typhus (caused by *R. prowazeki*) is spread among humans by the human body louse (*Pediculus humanus corporis*). Outbreaks of epidemic typhus last occurred in the United States in the 19th century. The freedom of the population from lice explains the absence of epidemics in the United States. Sporadic cases in the United States have been associated with flying squirrel contact. The location of the disease is now limited to the Balkans and Middle East, North Africa, Asia, Mexico, and the Andes. In the epidemic form, all age groups are affected.

Rickettsiae may remain viable for as long as 20 years in the tissues of recovered patients without manifest symptoms. Brill-Zinsser disease is a recrudescence of epidemic typhus that occurs years after the initial attack and may cause a new epidemic.

Murine typhus (*R. typhi*) is worldwide in distribution and is distributed to humans by fleas. The disease is most prevalent in southeastern and Gulf Coast states and among individuals whose occupations bring them into rat-infested areas. The disease is most common in the late summer and fall months.

Diagnosis

A presumptive diagnosis of typhus fever can be made on the basis of the characteristic skin rash and signs of involvement of the nervous system. The diagnosis is established by the Weil-Felix reaction, which becomes positive in the fifth to eighth day of the disease. The titer rises in the first few weeks of the convalescence and then falls. Antibodies to specific rickettsiae can be demonstrated by complement fixation, microagglutination, or immunofluorescence reactions.

Course and Prognosis

The course of typhus fever usually extends over 2 to 3 weeks. Death from epidemic typhus usually occurs between the 9th and 18th day of illness. In patients who recover, the temperature begins to fall after 14 to 18 days and reaches normal levels in 2 to 4 days. Complications include bronchitis and bronchopneumonia, myocardial degeneration, gangrene of the skin or limbs, and thrombosis of large abdominal, pulmonary, or cerebral vessels.

The prognosis of epidemic typhus depends on the patient's age and immunization status. The disease is usually mild in children younger than 10. After the third decade, mortality increases steadily with each decade. Death is usually due to the development of pneumonia, circulatory collapse, and renal failure. The mortality rate for murine typhus in the United States is low (less than 1%). There are no neurologic residua in patients who recover.

Scrub Typhus

Scrub typhus is an infectious disease caused by *R. tsutsugamushi* (*R. orientalis*), which is transmitted to humans by the bite of larval trombiculid mites (chiggers). It resembles the other rickettsial diseases and is characterized by sudden onset of fever, cutaneous eruption, and the presence of an ulcerative lesion (eschar) at the site of attachment of the chigger.

Epidemiology

The disease is limited to eastern and southeastern Asia, India, and northern Australia and adjacent islands.

Symptoms and Signs

The disease begins abruptly, after an incubation period of 10 to 12 days, with fever, chills, and headache. The headache increases in intensity and may become severe. Conjunctival congestion, moderate generalized lymphadenopathy, deafness, apathy, and anorexia are common symptoms. Delirium, coma, restlessness, and muscular twitchings are present in severe cases. A primary lesion (the eschar) is seen in nearly all cases and represents the former site of attachment of the infected mite. There may be multiple eschars. The cutaneous rash appears between the fifth and eighth day of the disease. The eruption is macular or maculopapular and nonhemorrhagic. The trunk is involved first with later extension to the limbs.

Diagnosis

The diagnosis is made on the basis of the development of typical symptoms, the presence of the characteristic eschar, and a rising titer to *Proteus* OXK in the Weil-Felix test during the second week of illness. Immunofluorescence testing with specific antigens may be diagnostic.

Course and Prognosis

In fatal cases, death usually occurs in the second or third week as a result of pneumonia, cardiac failure, or cerebral involvement. In the preantibiotic era, mortality could reach 60%, depending on geographic locale and virulence of the strain. Deaths are rare with appropriate antibiotic treatment.

In patients who recover, the temperature begins to fall at the end of the second or third week. Permanent residua are not common, but the period of convalescence may extend over several months.

Human Ehrlichiosis

The nature and extent of infections in humans with rickettsia of the genus *Ehrlichia* is still not fully determined. These organisms appear to infect leukocytes. Two forms of human infection have been identified. One species, *E. chaffeensis*, is associated with human monocytic ehrlichiosis (HME) and the organism can be preferentially found in these cells. The agent of human granulocytic ehrlichiosis (HGE) has not yet been assigned a species. Serologically it cross-reacts with *E. equus*, but it is not clear if it is the same species. Both human infections are detectable in the appropriate cells as coccobacillary forms. It has become possible to cultivate the organisms, and PCR reactions are also coming into use to detect infection. Most studies still rely on antibody detection. *E. chaffeensis* appears to be transmitted by *Amblyomma americanum* (lone star tick) and possibly by *D. variabilis*, whereas the human granulocytic ehrlichiosis agent is transmitted by *Ixodid* ticks and probably *Dermacentor andersonii*.

Epidemiology

The epidemiologic range for both agents appears to be extending. Whether this is an actual phenomenon or due to an heightened awareness of the infection is still unclear. HME is more common in the South and Southeast, whereas HGE was first found in the Midwest. Now cases have been reported from New England and New York State, in keeping with the distribution of *Ixodes scapularis*. Coinfection of HGE with *Borrelia burgdorferi* and HME with Rocky Mountain spotted fever has already been reported.

Symptoms and Signs

Infection of both agents usually presents as a febrile systemic process often associated with myalgias and headaches. Changes in mental status and ataxia have also been noted and are correlated with more serious illness. Rashes have been reported in about 20% of cases. This makes it difficult to distinguish the illness from Rocky Mountain spotted fever, whose distribution overlaps with *E. chaffeensis*. CSF pleocytosis and elevated proteins have been reported and appear to correlate with altered mental status.

Diagnosis

Because of the nonspecific nature of the symptoms and signs, a high index of suspicion is required. A history of exposure to ticks may be helpful, but epidemiologic studies have shown serologic evidence of infection usually is not correlated with known tick bites. As might be anticipated, lymphopenia is often a feature of *E. chaffeensis* infection, whereas granulocytopenia is usually noted with the HGE agent. Elevated hepatic enzymes are usually present. The rickettsiae can often be found in infected leukocytes. Confirmation of the diagnosis is by antibody titers or immunofluorescent detection of the intracellular organisms. PCR detection of the organisms' DNA, when it is more widely available, will be an important technique because of sensitivity and rapidity. Culturing of the agents is now also possible but is not as sensitive as PCR.

Course and Prognosis

A complete understanding of the course of both HME and HGE has yet to be determined. Initially, a high proportion of reported cases was fatal in both HME and HGE. However, serologic studies indicate asymptomatic or minor infections are common. Clinically, it has also been found that some cases may be self-limited, even without treatment. Treatment with tetracycline or doxycycline results in rapid improvement. Therefore, prognosis appears to be good, if the diagnosis is promptly made and treatment started. Whether chloramphenicol will be an acceptable alternative antibiotic has yet to be established.

OTHER BACTERIAL INFECTIONS

Brucellosis

Brucellosis (undulant fever) is a disease with protean manifestation due to infection with short, slender, rod-shaped, gram-negative microorganisms of the genus *Brucella*. The infection is transmitted to humans from animals, usually cattle or swine. The illness is prone to occur in slaughterhouse workers, livestock producers, veterinarians, and persons who ingest unpasteurized milk or milk products. An acute febrile illness is characteristic of the early stages of the disease. The common symptoms include chilly sensations, sweats, fever, weakness, and generalized malaise; 70% of patients experience body aches and nearly 50% complain of headache. Physical signs of lymphadenopathy, splenomegaly, hepatomegaly, and tenderness of the spine, however, are infrequent, occurring in less than 25% of cases. The early constitutional symptoms are followed by the subacute and chronic stages in about 15% to 20% of patients with localized infection of the bones, joints, lungs, kidneys, liver, lymph nodes, and other organs.

Involvement of the nervous system is not common. Cases have been reported with meningitis and sometimes with accompanying cranial nerve paresis,

meningoencephalitis, meningomyelitis, optic neuritis, and peripheral neuritis. Brain abscesses also have been reported.

The CSF in reported cases is under increased pressure, with a pleocytosis varying from a few to several hundred cells. The protein content is moderately to greatly increased, and the sugar content is decreased. The CSF has increased gamma globulin levels and often contains *Brucella*-agglutinating antibodies.

In the few patients with CNS involvement who came to autopsy, there was a subacute meningitis with perivascular infiltrations, thickening of the vessels in the brain and spinal cord, and degenerative changes in the white and gray matter. Organisms have been cultured from the CSF of a few patients.

The diagnosis is made from a history of previous symptoms of the disease, culture of the organisms from the blood or CSF, and serologic testing. Treatment is with doxycycline or other tetracycline plus an aminoglycoside. Trimethoprim/sulfoxazole is an alternative to the tetracycline.

Behçet Syndrome

An inflammatory disorder of unknown cause, characterized by the occurrence of relapsing uveitis and recurrent genital and oral ulcers, was described by Behçet in 1937. The disease may involve the nervous system, skin, joints, peripheral blood vessels, and other organs. Evidence of CNS involvement is present in 25% to 30% of patients. Neurologic symptoms antedate the more diagnostic criteria of aphthous stomatitis, genital ulcerations, and uveitis in only 5% of cases. Pathologic confirmation of cerebral involvement has been obtained in a few cases. The disease appears to have a predilection for young adult men.

Etiology and Pathology

The cause of Behçet syndrome is unknown. No infectious agent has been isolated consistently, although there have been several reports of a virus having been recovered from patients with the disease. Circulating immune complexes of the IgA and IgG variety may be detected in patients' serums. The disease is associated with HLA-B5 tissue type in Japan and the Mediterranean nations.

In patients studied at necropsy, there was a mild inflammatory reaction in the meninges and in the perivascular spaces of the cerebrum, basal ganglia, brainstem, and cerebellum and degenerative changes in the ganglion cells. Inflammatory changes were also found in the iris, choroid, retina, and optic nerve.

Incidence

The disease is common in northern Japan, Turkey, and Israel; the incidence in Japan is 1 in 10,000. The syndrome is seen less commonly in the United States. An annual incidence of 1 in 300,000 was determined for Olmstead County, Minnesota. The age at onset is in the third and fourth decades of life; men are more frequently affected than women. The exact incidence of neurologic symptoms is not known, but it approximates 10% of affected individuals.

Symptoms and Signs

The ocular signs include keratoconjunctivitis, iritis, hypopyon, uveitis, and hemorrhage into the vitreous. Ocular symptoms occur in 90% of patients and may progress to total blindness in one or both eyes. The cutaneous lesions are in the nature of painful recurrent and indolent ulcers, which are most commonly found on the genitalia or the buccal mucosa. Virtually all patients have recurrent oral aphthous ulcers. Arthritis occurs in about 50% of patients. Furunculosis, erythema nodosum, thrombophlebitis, and nonspecific skin sensitivity are also common. Patients with Behçet syndrome often develop a pustule surrounded by erythema at the site of a needle puncture; when present, the finding is considered virtually pathognomonic.

Any portion of the nervous system may be affected. Cranial nerve palsies are common. Other symptoms and signs include papilledema, convulsions, mental confusion, coma, aphasia, hemiparesis, quadriplegia, pseudobulbar palsy, and evidence of involvement of the basal ganglia, cerebellum, or spinal cord.

Laboratory Data

A low-grade fever is common during the acute exacerbations of the disease. Fever may be accompanied by an elevation of the sedimentation rate, anemia, and a slight leukocytosis in the blood. A polyclonal increase in serum gamma globulin may be present. Coagulation profile may disclose elevated levels of fibrinogen and factor VIII.

The CSF pressure may be slightly increased. There is a pleocytosis of a mild or moderate degree and a moderate increase in the protein content. CSF sugar, when reported, has been normal. The serologic tests for syphilis are negative in the blood and CSF. Elevation of the CSF gamma globulin content has been reported. CSF cultures have been negative. Mild diffuse abnormalities may be found on the electroencephalogram. CT may demonstrate lesions of decreased density that may be contrast enhancing.

Diagnosis

The diagnosis is based on the occurrence of signs of a meningoencephalitis in combination with the characteristic cutaneous and ocular lesions. The disease may simulate multiple sclerosis with multifocal involvement of the nervous system, including the brainstem, cerebellum, and corticospinal tract. Syphilis is excluded by the negative serologic tests. Sarcoidosis is excluded by the absence of other signs of this disease: lack of characteristic histologic changes in biopsied lymph node, liver, or other tissues and the presence of serum angiotensin-converting enzyme.

Course

The course of the disease is characterized by a series of remissions and exacerbations extending over several years. During the period of remission, all symptoms may improve greatly. Unilateral amblyopia or complete blindness may result from the ocular lesions. Residuals of the neurologic lesions are not uncommon.

Neurologic and posterior uveal tract lesions indicate a poor prognosis. Death has occurred from the disease, chiefly when the CNS became involved. Permanent remission of symptoms has not been reported.

Treatment

Various antibiotics, chemotherapy, and corticosteroids have been used in the treatment, but there is no evidence that any of these forms of therapy have any effect on the course of the disease. When the neurologic components of the disease are life threatening, immunosuppressive therapy may be considered. Therapy is difficult to assess because of the variable natural course.

Vogt-Koyanagi-Harada Syndrome

A relatively rare disease characterized by uveitis, retinal hemorrhages and detachment, depigmentation of the skin and hair, and signs of involvement of the nervous system was reported by Vogt, Koyanagi, and Harada in the 1920s. The dermatologic signs include poliosis and canities (patchy whitening of eyelashes, eyebrows, and scalp hair), alopecia (patchy loss of hair), and vitiligo (patchy depigmentation of skin).

The nervous system is affected in practically all cases. The neurologic symptoms are caused by an inflammatory adhesive arachnoiditis. The most common patient complaint is headache, sometimes accompanied by dizziness, fatigue, and somnolence. Neurosensory deafness, hemiplegia, ocular palsies, psychotic manifestations, and meningeal signs may occur. The CSF is under increased pressure. There is a moderate degree of lymphocytic pleocytosis. The CSF protein content is normal or slightly elevated; an elevated gamma globulin has been reported. The CSF glucose level is normal. The period of activity of the process lasts for 6 to 12 months and is followed by a recrudescence of the ophthalmic and neurologic signs.

The cause of the disease is unknown. It has been suggested that it is caused by a viral infection, but proof for this is lacking. The eye lesions are similar to those of

sympathetic ophthalmia. There is no specific therapy, but some reports suggest that administration of corticosteroids may be of value.

Mollaret Meningitis

Patients with recurrent episodes of benign aseptic meningitis were first described by Mollaret in 1944. The disease is characterized by repeated, short-lived, spontaneous, remitting attacks of headache and by nuchal rigidity. Between attacks, the patient enjoys good health. The meningitis episodes usually last 2 or 3 days. Most are characterized by a mild meningitis without associated neurologic abnormalities. Transient neurologic disturbances (coma, seizures, syncope, diplopia, dysarthria, disequilibrium, facial paralysis, anisocoria, and extensor plantar responses) have been reported. The patient's body temperature is moderately elevated with a maximum of 104°F (40°C). Neck stiffness and the signs of meningeal irritation are present. The first attack may appear at any age between childhood and late adult years. Both sexes are equally affected. The episodes usually last for 3 to 5 years.

During the attacks, there is a CSF pleocytosis and a slight elevation of the protein content. The CSF sugar content is normal. The cell counts range from 200 to several thousand/mm³; most cells are mononuclear. Large fragile endothelial cells are found in the CSF in the early phases of the disease; their presence is variable and is not considered essential for the diagnosis.

Proposed etiologic agents in individual cases have included herpes simplex type I, epidermoid cyst, and histoplasmosis, but none has been found with consistency. In recent years, detection of herpes simplex type II genome by PCR has been regularly, but not uniformly, reported in recurrent aseptic meningitis to which the name Mollaret meningitis is often applied. It is uncertain whether this constitutes a dilution of the eponym. It is therefore still not possible to determine whether Mollaret meningitis is a syndrome of multiple etiologies or a disease that excludes known causes.

The differential diagnosis of the condition includes recurrent bacterial meningitis, recurrent viral meningitis, sarcoidosis, hydatid cyst, fungal meningitis, intracranial tumors, Behçet syndrome, and the Vogt-Koyanagi-Harada syndrome. The latter two conditions may be differentiated by eye and skin lesions and associated findings.

Patients with Mollaret meningitis always recover rapidly and spontaneously without specific therapy. There is no effective therapy for shortening the attack or preventing fresh attacks.

Aseptic Meningeal Reaction

Aseptic meningeal reaction (sympathetic meningitis, meningitis serosa) is a term used to describe those cases with evidence of a meningeal reaction in the CSF in the absence of any infecting organism. Four general classes of cases fall into this category: those in which the meningeal reaction is due to a septic or necrotic focus within the skull or spinal canal (parameningeal infection), those in which the meningeal reaction is due to the introduction of foreign substances (e.g., air, dyes, drugs, blood) into the subarachnoid space, those in association with connective tissue disorders, and those associated with systemically administered medications (e.g., trimethoprim/sulfoxazole or nonsteroidal anti-inflammatory agents).

The symptoms that are present in the patients in the first group are associated with the infection or morbid process in the skull or spinal cavity. Only occasionally are there any symptoms and signs of meningeal irritation.

In the second group of patients, where the meningeal reaction is due to the introduction of foreign substances into the subarachnoid space, fever, headache, and stiffness of the neck may occur. The appearance of these symptoms leads to the suspicion that an actual infection of the meninges has been produced by the inadvertent introduction of pathogenic organisms. The normal sugar content of the CSF and the absence of organisms on culture establish the nature of the meningeal reaction.

An aseptic meningeal reaction may complicate the course of systemic lupus erythematosus and periarteritis nodosa. In certain instances, the meningeal reaction in patients with systemic lupus erythematosus may be induced by nonsteroidal anti-inflammatory drugs or azathioprine. An aseptic meningeal reaction may also occur in the Sjögren syndrome.

The findings in the CSF that are characteristic of an aseptic meningeal reaction are an increase in pressure, a varying degree of pleocytosis (10 to 4,000 cell/mm³), a slight or moderate increase in the protein content, a normal sugar content, and the absence of organisms on culture. (Exceptionally, and without explanation, the aseptic meningeal reaction of systemic lupus erythematosus may be accompanied by low CSF sugar values.) With a severe degree of meningeal reaction, the CSF may be purulent in appearance and may contain several thousand cells per cubic milliliter with a predominance of polymorphonuclear leukocytes. With a lesser degree of meningeal reaction, the CSF may be normal in appearance or only slightly cloudy and may contain a moderate number of cells (10 to several hundred/mm³), with lymphocytes being the predominating cell type in the CSF with less than 100 cells/mm³.

The pathogenesis of the changes in the CSF is not clearly understood. The septic foci in the head that are more commonly associated with an aseptic meningeal reaction are septic thrombosis of the intracranial venous sinuses; osteomyelitis of the spine or skull; extradural, subdural, or intracerebral abscesses; or septic cerebral emboli. Nonseptic foci of necrosis are accompanied only rarely by an aseptic meningeal reaction. Occasionally, patients with an intracerebral tumor or cerebral hemorrhage that is near to the ventricular walls may show the similar changes in the CSF.

The diagnosis of an aseptic meningeal reaction in patients with a septic or necrotic focus in the skull or spinal cord is important in that it directs attention to the presence of this focus and the necessity for appropriate surgical and medical therapy before the meninges are actually invaded by the infectious process or before other cerebral or spinal complications develop.

Meningism

Coincidental with the onset of any acute infectious diseases in childhood or young adult life there may be headache, stiffness of the neck, Kernig sign, and, rarely, delirium, convulsions, or coma. The appearance of these symptoms may lead to the tentative diagnosis of an acute meningitis or encephalitis.

Meningism refers to the syndrome of headache and signs of meningeal irritation in patients with an acute febrile illness, usually of a viral nature, in whom the CSF is commonly under increased pressure but normal in other respects. The condition may prove diagnostically confusing.

There is no completely satisfactory explanation for the syndrome. Acute hypotonicity of the patient's serum, inappropriate secretion of antidiuretic hormone, and an increased formation of CSF have been considered as possible causes. The characteristic findings on lumbar puncture are a slight or moderate increase in pressure, a clear colorless CSF that contains no cells, and a moderate reduction in the protein content of the CSF.

The condition is brief in duration. Spinal puncture, which is usually performed as a diagnostic measure in these cases, is the only therapy necessary for the relief of the symptoms. The reduction of pressure by the removal of CSF results in the disappearance of symptoms. Rarely is more than one puncture necessary.

Mycoplasma pneumoniae Infection

Mycoplasmas, originally called pleuropneumonia-like organisms, lack a cell wall. Individual mycoplasmas are bounded by a unit membrane that encloses the cytoplasm, DNA, RNA, and other cellular components. They are the smallest of free-living organisms and are resistant to penicillin and other cell wall-active antimicrobials.

Of mycoplasmas that infect humans, *M. pneumoniae* is the only species that has been clearly shown to be a significant cause of disease. It is a major cause of acute respiratory disease, including pneumonia. A variety of neurologic conditions have been described in association with *M. pneumoniae* infection: meningitis, encephalitis, postinfectious leukoencephalitis, acute cerebellar ataxia, transverse myelitis, ascending polyneuritis, radiculopathy, cranial neuropathy, and acute psychosis. The most common neurologic condition appears to be meningitis or meningoencephalitis with alterations in mental status. The neurologic features associated with *M. pneumoniae* infection, however, are so diverse that the correct diagnosis cannot be made on clinical grounds alone. The CSF usually contains polymorphonuclear leukocytes and mononuclear cells in varying proportions. The CSF has a normal or mildly elevated protein content and a normal glucose level. Bacterial, viral, and mycoplasma cultures of the CSF are usually sterile. However, detection of mycoplasma in tissue or CSF has been accomplished. Retrospective

diagnosis can be made by cold isohemagglutinins for human type O erythrocytes. These can be detected in about 50% of patients during the second week of illness; they are the first antibodies to disappear. Specific antibodies can also be demonstrated.

Tetracycline and erythromycin are the drugs of choice for *M. pneumoniae* infections of a severe nature. It is not known if the postinfectious neurologic complications benefit from antimicrobial treatment.

Legionella pneumophila Infection

L. pneumophila is a poorly staining gram-negative bacterium that either does not grow or grows very slowly on most artificial media. The organism was first isolated from fatal cases of pneumonia among persons attending an American Legion Convention in Philadelphia in 1976. The bacterium is acquired by inhalation of contaminated aerosols or dust from air-conditioning systems, water, or soil.

Symptoms and Signs

Pneumonia is the most typical systemic manifestation of infection. Upper respiratory infection, a severe influenza-like syndrome (Pontiac fever), and gastrointestinal disease may also occur.

Several neurologic conditions have been described in association with *L. pneumophila* infection (Legionnaires' disease, legionellosis): acute encephalomyelitis, pronounced cerebellar deficit, chorea, and peripheral neuropathy. Confusion, delirium, and hallucinations are common symptoms. The pathophysiology of these syndromes is unclear because bacteria rarely have been demonstrated in the CNS. Myoglobinuria and elevated serum creatine kinase levels also have been reported.

Laboratory Data

L. pneumophila is rarely recovered from pleural fluid, sputum, or blood; it frequently can be isolated from respiratory secretions by transtracheal aspiration or bronchoalveolar lavage and lung biopsy tissue. A retrospective diagnosis can be made by a significant rise in specific serum antibodies detected by immunofluorescence.

Treatment

The treatment of choice is administration of erythromycin. Relapses are uncommon if treatment is continued for 14 days. When relapses occur, they usually respond to a second course of the antibiotic.

The true incidence of neurologic involvement in Legionnaires' disease is still unknown. The neurologic deficit is known to be reversible, but little exact information about recovery is available.

CHAPTER 22. FOCAL INFECTIONS

GARY L. BERNARDINI

[Malignant External Otitis and Osteomyelitis of the Base of the Skull](#)
[Brain Abscess and Subdural Empyema](#)
[Suggested Readings](#)

MALIGNANT EXTERNAL OTITIS AND OSTEOMYELITIS OF THE BASE OF THE SKULL

Malignant external otitis is an infection that begins in the external auditory canal, penetrates the epithelium, and spreads to the surrounding soft tissue to cause cellulitis and abscess. If untreated, the infection extends to the temporomandibular joint, mastoid, or more commonly soft tissues below the temporal bone. The facial nerve may be affected as the first symptom in up to 30% of patients. Other common symptoms are severe otalgia, purulent otorrhea, hearing loss, and painful swelling of surrounding tissues. Rarely, dysphagia may result from lesions of cranial nerves IX through XII, and the findings may be mistaken for laryngeal carcinoma. Fever and weight loss are uncommon. Mastoid tenderness is evident on examination. The syndrome is most frequently observed in elderly diabetic patients and is also seen in people infected with human immunodeficiency virus.

Laboratory evaluation shows a mildly elevated or normal white blood cell count. The erythrocyte sedimentation rate is almost always elevated (>50 mm/h). Computed tomography (CT) is most useful in evaluating evidence of bony erosion, but films may be normal early in the illness. Magnetic resonance imaging (MRI), with and without gadolinium, is the study of choice. Isotope bone scans are sensitive but not specific. Newer techniques using technetium (^{99m}Tc) methylene diphosphonate and gallium-67 single photon emission CT may be more sensitive and accurate in early detection of malignant external otitis and monitoring response to therapy.

In most cases, *Pseudomonas aeruginosa* is the causative organism. In human immunodeficiency virus-positive individuals or in AIDS, either *P. aeruginosa* or the fungus *Aspergillus fumigatus* may be isolated. In the preantibiotic era, mortality rates were greater than 50% and surgical debridement was the treatment of choice. Standard treatment with intravenous antibiotics consisted of an antipseudomonal penicillin for 4 to 8 weeks combined with an aminoglycoside for at least 2 weeks or, if tolerated, 4 to 6 weeks. Current successful treatment is based on single-drug therapy with either the antipseudomonal third-generation cephalosporin ceftazidime or the fluoroquinolone ciprofloxacin in patients with limited external otitis (i.e., without bony erosion or cranial neuropathy). Double-antibiotic therapy is considered with more extensive lesions. Drug-resistant strains have been found for both ceftazidime and ciprofloxacin. Despite these new treatments, the mortality rate is still 10% to 20% and may be as high as 50% if cranial nerves are involved. If untreated or inadequately treated, malignant external otitis can result in osteomyelitis of the base of the skull, abscess formation, meningitis, and death.

Osteomyelitis of the base of the skull is a rare complication of malignant external otitis, chronic mastoiditis, or paranasal sinus infection. As with malignant otitis, the patients are usually elderly, diabetic, or immunocompromised. Symptoms include headache, otalgia, hearing loss, and otorrhea, but patients are frequently without fever. Osteomyelitis may occur in conjunction with otitis but usually appears weeks or months after starting antibiotics. As the process spreads, cranial nerves may be affected, especially the VII and VIII nerves. Extension of skull base osteomyelitis to the jugular foramen or hypoglossal canal can affect cranial nerves IX through XII, leading to dysphagia. In advanced cases, spread to the petrous pyramid may affect III, IV, V, and VI cranial nerves to cause ocular palsies or trigeminal neuralgia.

Laboratory abnormalities include a normal or slightly elevated white blood cell count and a high erythrocyte sedimentation rate. Thin-cut CT sections through the skull base and temporal bones play an important role in the diagnosis of osteomyelitis and assessing the extent of disease. Carcinoma of the ear canal may cause similar clinical and radiographic findings, and bone biopsy may be needed if there is no response to appropriate antibiotic therapy. MRI is useful in delineating soft tissue involvement. Technetium bone scanning is a sensitive indicator of osteomyelitis but is not helpful in determining resolution of disease. Gallium-67 scans can be useful in tracking resolution of disease over time. Neither bone nor gallium scans are useful in determining the exact extent of the infection. *P. aeruginosa* is the typical causative organism, but *Staphylococcus aureus* or other organisms such as *Staphylococcus epidermidis*, *Proteus*, *Salmonella*, *Mycobacterium*, *Aspergillus*, and *Candida* have been implicated rarely.

Therapy for osteomyelitis consists of intravenous administration of antibiotics, usually an antipseudomonal penicillin or cephalosporin in combination with an aminoglycoside to provide synergy and to prevent the emergence of drug-resistant bacteria. Ciprofloxacin has been effective when used alone or with other antibiotics. Ceftazidime has bactericidal activity against *Pseudomonas* and may be used as monotherapy. Because the disease is usually extensive, conservative management of skull base osteomyelitis is still an extended course of two-drug therapy. Monthly gallium scans may help to determine the response and duration of antibiotic therapy. In refractory cases, hyperbaric oxygen has been used as adjuvant therapy. Antibiotics should be continued for at least 1 week after the gallium scan becomes normal. Follow-up gallium scans may be performed 1 week after completion of antibiotic therapy to detect early recurrence and at 3 months for late recurrence. Mortality rates of 40% have been reported, but with prolonged antibiotic therapy, complete cure can be achieved.

BRAIN ABSCESS AND SUBDURAL EMPYEMA

Brain Abscess

Incapsulated or free pus in the substance of the brain after an acute focal purulent infection is known as brain abscess. Abscesses vary in size from a microscopic collection of inflammatory cells to an area of purulent necrosis involving the major part of one hemisphere. Abscess of the brain has been known for over 200 years, and surgical treatment started with Macewen in 1880.

Advances in the diagnosis and treatment of brain abscesses have been achieved with the use of CT, stereotactic brain biopsy and aspiration, and new antimicrobials.

Etiology

Brain abscesses are classified on the basis of the likely entry point of the infection. For example, brain abscesses arise most commonly as direct extension from cranial infections (mastoid, teeth, paranasal sinuses, or osteomyelitis of the skull), from infections after fracture of the skull or neurosurgical procedures, or as metastases from infection elsewhere in the body. Brain abscess is only rarely a complication of bacterial meningitis, except in infants. Infections in the middle ear or mastoid may spread to the cerebellum or temporal lobe through involvement of the bone and meninges or by seeding of bacteria through valveless emissary veins that drain these regions, with or without extradural or subdural infection or thrombosis of the lateral sinus. An abscess in one hemisphere can follow infection in the contralateral mastoid, presumably by hematogenous spread of the organism. Infection in the frontal, ethmoid, or rarely the maxillary sinuses spreads to the frontal lobes through erosion of the skull. Subdural or extradural infection or thrombosis of the venous sinuses also may be present. Approximately 20% to 30% of brain abscesses may have no obvious source identified.

Metastatic seeding from a remote site may cause brain abscess (e.g., arising in the lungs, by bronchiectasis or lung abscess) or less frequently in bacterial endocarditis. Other sources include the tonsils and upper respiratory tract, from which the infection can reach the brain along the carotid sheath, or after urinary tract or intraabdominal infections. After metastatic spread, the cerebral lesions are commonly multiple and are found in the distribution of the middle cerebral artery. Congenital heart disease and pulmonary arteriovenous fistulas (as in hereditary hemorrhagic telangiectasia) predispose to brain abscess. In these two disorders, infected venous blood bypasses the pulmonary filtration system and gains access to the cerebral arterial system.

The occurrence of abscesses of the brain after penetrating brain injury is low, although entry of bacteria into the brain is common after such injuries with the introduction of infected missiles or tissues into the brain through compound fractures of the skull. In children, penetration of a lead pencil tip through the thin squamous portion of the temporal bone have resulted in abscess around the foreign material in the frontal lobe.

The infecting organism may be any of the common pyogenic bacteria depending on the site of entry; the most common are *S. aureus*, streptococci (anaerobic, aerobic, or microaerophilic species), *Enterobacteriaceae*, *Pseudomonas*, and anaerobes such as *Bacteroides*. In infants, gram-negative organisms are most frequent offenders. After penetrating head injury, abscess formation is usually due to *S. aureus*, streptococci, *Enterobacteriaceae*, or *Clostridium* species; *S. epidermidis* infection follows neurosurgical procedures. In the immunocompromised host, *Toxoplasma*, fungi, *Nocardia*, and *Enterobacteriaceae* are frequently found.

Pneumococci, meningococci, and *Hemophilus influenzae* are major causes of bacterial meningitis but are rarely recovered from a brain abscess. Brain abscess is an infrequent complication of parasitic infection such as *Entamoeba histolytica*. Cultures may be sterile in patients who have received antimicrobial therapy before biopsy, but any material obtained should be sent to the laboratory. A positive Gram stain may guide therapy even when the culture is negative.

Pathology

The pathologic changes in brain abscess are similar regardless of the origin: direct extension to the brain from epidural or subdural infection, retrograde thrombosis of veins, or arterial metastasis (Fig. 22.1). Four stages of maturation are recognized. Within the first 3 days, suppurative inflammation of brain tissue is characterized by early cerebritis and either a patchy or nonenhancing hypodensity on CT or MRI. The progression from late cerebritis (with an area of central necrosis, edema, and ring enhancement on CT and MRI) to early capsule formation and final maturation of the capsule takes about 2 weeks. When host defenses control the spread of the infection, macroglia and fibroblasts proliferate in an attempt to surround the infected and necrotic tissue, and granulation tissue and fibrous encapsulation develops. The capsule is thicker on the cortical surface than on the ventricular side. If the capsule ruptures, purulent material is released into the ventricular system with a high mortality rate. Edema of adjacent cerebrum or the entire hemisphere is common (Fig. 22.2).

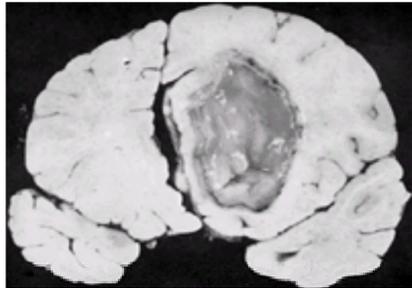

FIG. 22.1. Brain abscess. Fresh abscess in frontal lobe secondary to pulmonary infection. (Courtesy of Dr. Abner Wolf.)

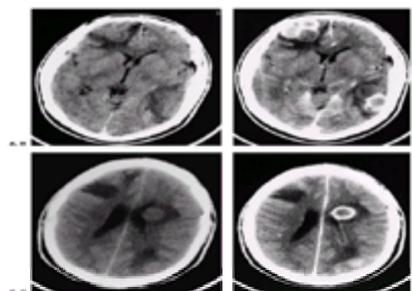

FIG. 22.2. Multiple brain abscesses. **A and B:** Multiple brain abscesses seen on computed tomography (CT) both before and after intravenous contrast. Symptoms started 2 weeks after dental cleaning with severe headache and drowsiness; isolates from an abscess revealed *Streptococcus viridans* sp. Note characteristic ring enhancement (**B**) and marked edema with midline shift (**A and B**) around three abscesses in the right frontal lobe; a daughter abscess shows less ring enhancement and is directed inward. In addition, there is a left temporoparietal ring-enhancing lesion, with possible adjacent early cerebritis lesion, with surrounding edema. **C and D:** A periventricular abscess in the same patient seen on a higher cut CT with and without contrast; note ependymal enhancement after the administration of contrast, indicating extension of the abscess into the left lateral ventricle. (Courtesy of Dr. L. Fontana.)

Incidence

Brain abscesses were common in the first half of the 20th century, but the introduction of effective therapy for purulent infection of the mastoid process and nasal sinuses has greatly reduced the incidence of all intracranial complications of these infections, including brain abscess. Brain abscesses constitute less than 2% of all intracranial surgery. Brain abscess may occur at any age but is still encountered in the first to third decades of life as a result of the high incidence of mastoid and nasal sinus disease in those years. Up to 25% of all cases affect children less than 15 years old, with a cluster in the 4- to 7-year-old age group, usually the result of cyanotic congenital heart disease or an otic source.

Symptoms and Signs

The symptoms of brain abscess are those of any expanding lesion in the brain, and headache is the most common symptom. The pain is a dull ache that is not localized. Fever is present in less than 50% of patients; many are afebrile. Edema of surrounding brain tissue can rapidly increase intracranial pressure so that worsening headache, nausea, and vomiting are early symptoms. Sudden worsening of preexisting headache with new onset of nuchal rigidity often heralds rupture of brain abscess into the ventricular space. Abrupt onset of a severe headache is less common with abscess and is more often associated with acute bacterial meningitis or subarachnoid hemorrhage. Seizures, focal or generalized, are common with abscess.

Focal signs, including altered mental status and hemiparesis, are seen in approximately 50% of patients depending on abscess location. Hemiparesis may be seen with lesions of the cerebral hemispheres. Apathy and mental confusion have been linked with abscesses in the frontal lobe. Hemianopia and aphasia, particularly anomia, are found when the temporal or parietooccipital lobes are involved. Ataxia, intention tremor, nystagmus, and other classic symptoms may be seen with cerebellar abscess. Frequently, however, the signs of an abscess in the cerebrum or cerebellum are limited to those of increased intracranial pressure (nausea, vomiting, and headache). Abscesses in the brainstem are rare. The classic findings of a brainstem syndrome are often lacking because the abscess tends to expand longitudinally along fiber tracts rather than transversely. Papilledema is present in only about 25% of all patients. Signs of injury to the III or VI cranial nerve are sometimes the result of increased intracranial pressure.

Subdural or, rarely, epidural infections in the frontal regions may give the same signs and symptoms as those of an abscess in the frontal lobe. Fever and focal seizures favor the diagnosis of subdural rather than intraparenchymal abscess.

Thrombosis of the lateral sinus often follows middle ear or mastoid infection and may be accompanied by seizures and signs of increased intracranial pressure, making the clinical differentiation between this condition and abscess of the temporal lobe or cerebrum difficult. With lateral sinus thrombosis, papilledema may be due to interference with the drainage of blood from the brain. Focal neurologic signs favor the diagnosis of abscess.

Diagnostic Tests

Brain abscess can be suspected clinically when seizures, focal neurologic signs, or increased intracranial pressure develop in a patient with congenital heart disease or with a known acute or chronic infection in the middle ear, mastoid, nasal sinuses, heart, or lungs. The diagnosis is supported by CT or MRI (Fig. 22.2 and Fig. 22.3).

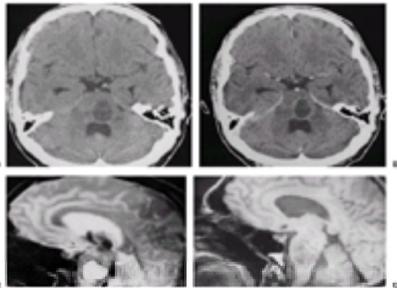

FIG. 22.3. Brainstem abscess. **A:** Axial noncontrast computed tomography demonstrates a round low-density left pontine lesion with mass effect on the fourth ventricle. **B:** Ring enhancement of the lesion after contrast is typical of an abscess. Sagittal T2-weighted (**C**) and sagittal T1-weighted (**D**) magnetic resonance images (MRIs) demonstrate the lesion to be cystic isointense to cerebrospinal fluid signal (compare with signal within the lateral ventricle). Note definition of the abscess rim in **D**. The sagittal MRIs are useful in planning a surgical approach through the fourth ventricle. (Courtesy of Drs. J. A. Bello and S. K. Hilal.)

Elevated white blood cell count or erythrocyte sedimentation rate is not reliably present. Blood cultures are positive in only 10% of patients but should always be obtained with suspected brain abscess, even in the absence of fever. Lumbar puncture is contraindicated in patients suspected of having a brain abscess because of the clear risk of transtentorial herniation. Older data on the results of cerebrospinal fluid (CSF) examination revealed elevated opening pressures and an aseptic meningeal reaction. In the series of Merritt and Fremont-Smith, opening pressure was over 200 mm H₂O in 70%. The CSF is usually clear but may be cloudy or turbid. The cell count varies from normal to 1,000 or more cells/mm³. In early unencapsulated abscesses near the ventricular or subarachnoid spaces, the cell count is high, with a high percentage of polymorphonuclear leukocytes. The cell count is normal or only slightly increased when the abscess is firmly encapsulated. The cell count in 34 patients at various stages of the disease varied between 4 and 800 cells with an average of 135 cells/mm³. The protein content is between 45 and 200 mg/dL. The CSF sugar content is normal.

Extension of the abscess to the meninges or ventricles is accompanied by an increase in the CSF cell count and other findings of acute meningitis or ventriculitis. Rupture of an abscess into the ventricles is signaled by a sudden rise of intracranial pressure and the presence of free pus in the CSF with a cell count of 20,000 to 50,000/mm³. A decrease in sugar content below 40 mg/dL indicates that the meninges have been invaded by bacteria. Only rarely are CSF cultures positive.

MRI and CT are the studies of choice, both for diagnosis and treatment of brain abscess. Plain radiographs of the skull may show separation of sutures in infants or children and an increase in the convolution markings. CT permits accurate localization of cerebritis or abscess and serial assessment of the size of the lesion, its demarcation, the extent of surrounding edema, and total mass effect. MRI with gadolinium is more sensitive and specific than contrast CT in diagnosing early cerebritis. With a mature encapsulated abscess, both contrast CT and MRI with gadolinium reveal the ring-enhancing mass with surrounding vasogenic edema. The differential diagnosis, based on the appearance of the lesion, includes glioblastoma, metastatic tumor, infarct, arteriovenous malformation, resolving hematoma, and granuloma. Features supporting the diagnosis of brain abscess include gas within the center of a ring-enhancing lesion, a thinner rim (<5 mm) than with brain tumors, and ependymal enhancement associated with ventriculitis or ventricular rupture (Fig. 22.2D). Thallium-201 brain single photon emission CT may be useful in differentiating intracerebral lymphoma from toxoplasma encephalitis in patients with AIDS.

Either CT or MRI may be useful in distinguishing abscess from mycotic aneurysms or herpes encephalitis, which may cause similar symptoms and signs. Mycotic aneurysm may arise from bacterial endocarditis with aseptic meningitis. CT or MRI may exclude abscess, but angiography may be necessary to identify the aneurysm before rupture. Herpes simplex encephalitis is manifest by headache, fever, and an acute temporal lobe or frontal lobe syndrome. On CT or MRI, the temporal lobe is swollen, with irregular lucency and patchy contrast enhancement.

Treatment

Before CT, the treatment of brain abscess was surgical, including incision and drainage through a burr hole or open craniotomy with marsupialization, packing the cavity, and complete extirpation. The introduction of CT revolutionized the management of brain abscess. CT made it possible to diagnose and localize cerebritis or abscess, dictate choice of treatment, and monitor patient response. The current recommended treatment for most brain abscesses is CT-guided stereotactic or free-hand needle aspiration with therapeutic drainage and obtaining diagnostic specimens for culture and special studies, along with appropriate antimicrobial therapy. Based on Gram stain results and presumptive source of the abscess, empiric antimicrobial therapy may be started. Early surgery is recommended, especially in cases with abscesses close to the ventricles into which the lesion may rupture. Nonoperative treatment may be appropriate for some patients who are clinically stable but poor surgical candidates or in those with surgically inaccessible lesions.

Open craniotomy is now performed infrequently and is reserved for patients with multiloculated abscesses that require complete excision or those with more resistant pathogens such as fungi or *Nocardia*.

Choosing the appropriate antimicrobial therapy depends on the ability of the drug to penetrate the abscess cavity and its activity against the suspected pathogen. Chloramphenicol was the standard therapy for brain abscesses at one time, but it lacks bactericidal activity and side effects are serious; it is used infrequently today. Brain abscesses that arise from intracranial extension of sinus infection, with usual isolates of microaerophilic streptococci and anaerobic organisms, can be treated with intravenous high-dose penicillin G (10 to 20 million units per day) and metronidazole. In some cases, cefotaxime or other cephalosporins is given in combination with metronidazole. Additional antibiotic coverage may be needed for some organisms (e.g., *Actinomyces* species) when the abscess is secondary to dental procedures or dental abscess. Special consideration of antimicrobial coverage for *Enterobacteriaceae* and *P. aeruginosa* should be made when an otogenic source of brain abscess is suspected. Vancomycin can be given initially in cases of brain abscess from neurosurgical procedures, likely due to *S. epidermidis*, while awaiting final culture results. It is generally recommended that parenteral antibiotics should be given for a total of 6 to 8 weeks, followed by an additional 2- to 3-month course of oral antibiotic therapy.

Clinical and CT or MRI responses are monitored to assess the effectiveness of medical therapy or the need for repeated surgery. Follow-up CT may show a small area of residual enhancement even after adequate antimicrobial therapy. Occasionally, a previous ring-enhancing lesion on CT disappears with medical management, suggesting that the reversible lesions are forms of suppurative cerebritis.

Seizures occur in up to 50% of patients with brain abscess early in the course. Anticonvulsants such as diphenylhydantoin or carbamazepine can be administered for prophylaxis or to prevent the recurrence of seizures. Generally, these agents are given for at least 3 months after surgery for abscess.

The use of corticosteroids is controversial. In patients with life-threatening cerebral edema or impending herniation, a short course of high-dose corticosteroids may be appropriate. Further deterioration with severe brain edema may require intubation with hyperventilation and the administration of intravenous mannitol to control elevated intracranial pressures. Prolonged use of corticosteroids is not recommended because the steroids may interfere with granulation tissue formation and reduce the concentration of antibiotics within the infected tissue.

Prognosis

The outcome of untreated brain abscess is, with rare exceptions, death. Mortality in pre-CT series varied from 35% to 55%. In the era of advanced neuroimaging with CT or MRI, the mortality rate of brain abscesses is 0 to 30%. Overall morbidity and mortality of brain abscess is related to the rapidity of onset of symptoms, the primary source of infection, the presence of single or multiple abscesses, and the patients neurologic status at the time of diagnosis. If the level of consciousness is depressed, patients tend to do poorly.

Immunocompromised individuals have worse outcomes and higher mortality rates. The highest death rate is found when the primary infection is in the lungs. Intraventricular rupture of a brain abscess is associated with high mortality rates exceeding 80%.

Sequelae of brain abscess include recurrence of the abscess or the development of new abscesses if the primary focus persists. Residual neurologic sequelae with hemiparesis, seizures, or intellectual or behavioral impairment is seen in 30% to 56% of patients.

Subdural Empyema

Subdural empyema is a collection of pus in the subdural space. Symptoms are similar to those of brain abscess. Subdural infection in adults usually arises from contiguous spread of infection; paranasal sinusitis is the most common source. Otitic infection, head trauma, and cranial surgery are other causes. Polymicrobial infection is common with pathogens similar to those of brain abscess, including *S. aureus* and both aerobic and anaerobic streptococci species. The infection spreads to the subdural space through retrograde thrombophlebitis via the venous sinuses or as direct extension through bone and dura. Once the infection develops, it may spread over the convexities and along the falx, although loculation is common. Associated complications include septic cortical vein thrombosis, brain or epidural abscess, and meningitis. The syndrome comprises an initial focal headache, fever, and, in 80% to 90% of patients, focal neurologic signs. The combination of fever, a rapid progressive neurologic deterioration, and focal seizures is particularly suggestive of this disorder. Symptoms of subdural empyema usually begin 1 to 2 weeks after a sinus infection.

Lumbar puncture is risky because of the mass effect. CT reveals a crescent-shaped area of hypodensity over a hemisphere, along the dura or adjoining the falx, with enhancement of the margins around the empyema after administration of contrast. MRI is preferred to CT for the delineation of the presence and extent of the subdural empyema and identifying concurrent intracranial infections.

Treatment of subdural empyema emphasizes rapid institution of antibiotics and early surgery. Intravenous antibiotics are given depending on the organism identified or, if unknown, with the same antibiotics used in brain abscess. Anticonvulsants are frequently required. There is controversy about the neurosurgical technique for drainage of subdural empyema. CT accurately localizes the pus collection, and some advocate drainage through selective burr holes. Others prefer craniotomy for more complete removal of the infection, especially when the empyema is loculated. Limited craniotomy is also used for placement of a tube into the subdural space and local infusion of appropriate antibiotics. Use of either burr hole or craniotomy for drainage of subdural empyema is individualized. The recommended duration of antibiotic therapy is 3 to 4 weeks after surgical drainage.

CHAPTER 23. VIRAL INFECTIONS

BURK JUBELT AND JAMES R. MILLER

[Acute Viral Infections](#)
[Chronic Viral Infections](#)
[Suggested Readings](#)

Although rabies has been known since ancient times and acute anterior poliomyelitis was recognized as a clinical entity in 1840, our knowledge of the role of viruses in the production of neurologic disease is of recent origin. In 1804, Zinke showed that rabies could be produced in a normal dog by inoculation of saliva from a rabid animal, but the filterable nature of rabies virus was not demonstrated until 1903. In 1908, Landsteiner and Popper produced a flaccid paralysis in monkeys by the injection of an emulsion of spinal cord from a fatal case of poliomyelitis. In the 1930s, filterable viruses were recovered from patients with epidemic encephalitis (arboviruses) and aseptic meningitis (lymphocytic choriomeningitis virus). With the use of electron microscopic, tissue culture, and immunologic techniques, many additional viruses that infect the nervous system have been recovered and characterized.

Although the list of viruses that cause human disease in epidemic or sporadic forms is extensive, most viral infections of the central nervous system (CNS) are uncommon complications of systemic illnesses caused by common human pathogens. After viral multiplication in extraneural tissues, dissemination to the CNS occurs by the hematogenous route or by spread along nerve fibers.

Viruses are *classified* according to their nucleic acid type, size, sensitivity to lipid solvents (enveloped versus nonenveloped), morphology, and mode of development in cells. The principal division is made according to whether the virus contains ribonucleic acid (RNA) or deoxyribonucleic acid (DNA). RNA viruses usually replicate within the cytoplasm of infected cells, whereas DNA viruses replicate in the nucleus. Members of almost every major animal virus group have been implicated in the production of neurologic illness in animals or humans ([Table 23.1](#)). The nature of the lesions produced varies with the virus and the conditions of infection. They may include neoplastic transformation, system degeneration, or congenital defects, such as cerebellar agenesis and aqueductal stenosis, as well as the inflammatory and destructive changes often considered typical of viral infection. In addition, the concept that a viral infection causes only an acute illness that quickly follows infection of the host has been altered by the demonstration that in slow viral infections illness may not appear until many years after exposure to the agent.

TABLE 23.1. VIRAL INFECTION OF THE NERVOUS SYSTEM

ACUTE VIRAL INFECTIONS

CNS Viral Syndromes

Acute viral infections of the nervous system can manifest clinically in three forms: viral (aseptic) meningitis, encephalitis, or myelitis, which is infrequent ([Table 23.2](#)). Viral *meningitis* is usually a self-limited illness characterized by signs of meningeal irritation, such as headache, photophobia, and neck stiffness. *Encephalitis* entails involvement of parenchymal brain tissue, as indicated by convulsive seizures, alterations in the state of consciousness, and focal neurologic abnormalities. When both meningeal and encephalitic findings are present, the term *meningoencephalitis* may be used. Viral infections may also localize to the parenchyma of the spinal cord, resulting in *myelitis*. Myelitis may occur from infection of spinal motor neurons (paralytic disease or poliomyelitis), sensory neurons, autonomic neurons (bladder paralysis), or demyelination of white matter (transverse myelitis). When both encephalitis and myelitis occur, the term *encephalomyelitis* is used. The cerebrospinal fluid (CSF) findings in these three acute viral syndromes are usually similar, consisting of an increase in pressure, pleocytosis of varying degree, a moderate protein content elevation, and a normal sugar content.

	Aseptic meningitis	Encephalitis	Paralytic disease	Total
Mumps	28	11	1	40
Lymphocytic choriomeningitis	7	0	0	7
Herpes simplex virus	2	7	0	9
Poliovirus	18	5	66	89
Coxsackievirus A	18	1	0	19
Coxsackievirus B	71	4	0	75
Echovirus	55	3	1	59
Arbovirus	3	5	0	8

From Buescher, et al. Central nervous system infections of viral etiology: the changing pattern. *Res Publ Assoc Res Nerv Ment Dis* 1968; 44:147-163; with permission.

TABLE 23.2. RELATIVE FREQUENCY OF MENINGITIS AND ENCEPHALITIS OF KNOWN VIRAL ETIOLOGY (NUMBER OF PATIENTS)

Common biologic properties of members of a specific virus group may dictate how they attack the CNS and the type of disease that they produce. For example, individual picornaviruses, such as poliovirus and echovirus, can cause similar clinical syndromes. Members of specific virus groups also show different predilections for cell types or regions of the nervous system. Thus, members of the myxovirus group attack ependymal cells, and herpes simplex virus (HSV) shows preference for frontal and temporal lobes.

The tendency for a disease to appear in an epidemic or sporadic form may also be related to the biologic properties of the virus. Most epidemic forms of meningitis, encephalitis, or myelitis are due to infection with enteroviruses or togaviruses. The enteroviruses (picornaviruses) are relatively acid- and heat-resistant, thus resulting in fecal-hand-oral transmission during the hotter months of the year. Many togaviruses require a multiplication phase in mosquitoes or ticks before they can infect people; human epidemics occur when climatic and other conditions favor a large population of infected insect vectors. Neurologic diseases due to members of other virus groups usually occur sporadically or as isolated instances that complicate viral infections of other organs or systems.

Diagnosis

Knowledge of whether an illness is occurring in an epidemic setting and of the seasonal occurrence of the different forms of acute viral infections may indicate the

methods to be used in detecting the infective agent. Infection with the picornaviruses or arboviruses tends to occur in the summer and early fall; other viruses, such as mumps, occur in late winter or spring.

The diagnosis can be made by a combination of virus isolation (inoculation of blood, nasopharyngeal washings, feces, CSF, or tissue suspensions into susceptible animals or tissue culture systems), serologic tests, and amplification of viral nucleic acids. Infectious virus particles in human fluids and tissues are usually few in number, and many viruses are easily disrupted and inactivated even at room temperature. Tissues and fluids to be used for virus isolation studies should therefore be frozen unless they can be immediately transferred to the laboratory in appropriate transport media.

The ability to recover virus from the CSF varies according to the nature of the agent. Some viruses, such as mumps virus, can frequently be isolated from the CSF, whereas other viruses, such as poliovirus and HSV type 1, are rarely recovered.

Serologic tests are applicable to all known acute viral diseases of the nervous system. Serum should be frozen and kept at a low temperature until the tests are done. The diagnosis of an acute viral infection and the establishment of the type of virus rest on the development of antibodies to the infection, traditionally a fourfold antibody rise. It is therefore necessary to show that antibodies are not present or are present only in low titer in the early stage of the illness and that they are present in high titer at a proper interval after the onset of symptoms. Several to many days are usually required for the development of antibodies; serum removed in the first few days of the illness can therefore serve as the control (acute-phase serum). Serum withdrawn in the convalescent stage, 3 to 5 weeks after the onset of the illness, may be used to determine whether antibodies have developed (convalescent-phase serum). When there is no change in titer, positive tests merely indicate that the individual has at some time in the past had an infection with this type of virus and that it probably is not the cause of the present illness.

If brain tissue from a patient is available in fatal cases or by brain biopsy, further studies can define the responsible virus. Brain sections can be analyzed by immunostaining techniques (immunofluorescence, immunoperoxidase) to determine whether specific viral antigens are present. Electron microscopy may indicate the presence of virus particles or components of specific morphology. Suspensions of brain and spinal cord can be injected into susceptible animals and tissue culture cell lines. In special instances, tissue cultures can be initiated from brain tissue itself. Such brain cell cultures can then be examined for the presence of viral antigens or infective virus. If an agent is recovered, final identification can be made by neutralization with known specific antiserum.

Any material used for viral isolation can also be used for amplification of viral nucleic acid by the polymerase chain reaction (PCR). Identification is then made by the use of complementary probes (hybridization).

Treatment

Antiviral chemotherapeutic agents are now available for several viruses: acyclovir (Zovirax) for HSV; acyclovir, famciclovir (Famvir), and foscarnet sodium (Foscavir) for varicella-zoster virus (VZV); ganciclovir sodium (Cytovene) and foscarnet for cytomegalovirus (CMV), and reverse transcriptase and protease inhibitors for human immunodeficiency virus (HIV).

Immunization procedures with either live attenuated vaccines or inactivated virus are readily available for rabies, poliomyelitis, hepatitis A and B, mumps, influenza, rubella, measles, chickenpox (varicella), and vaccinia. Immunization against the arboviruses is used mainly to protect laboratory workers and military personnel.

Although additional antiviral chemotherapeutic agents will likely become available in the future, vector control and mass immunization now seem to be the most practical means of effective control.

Enterovirus (Picornavirus) Infections

Picornaviruses are small, nonenveloped RNA viruses that multiply in the cytoplasm of cells. They are the smallest RNA viruses, hence the name "pico (small) RNA virus." Human picornaviruses can be divided into three subgroups: enteroviruses, found primarily in the gastrointestinal tract; rhinoviruses, found in the nasopharynx; and hepatitis A viruses (hepatoviruses). The enteroviruses comprise the *polioviruses*, *coxsackieviruses*, and *echoviruses*, all of which are capable of producing inflammation in the CNS. Recently, identified enteroviruses have been named as *unclassified enteroviruses 68 to 71*. CNS disease has occurred with enteroviruses 70 and 71 and with hepatitis A virus.

The enteroviruses are resistant to the acid and bile of intestinal contents and may survive for long periods in sewage or water. They grow only in primate cells and are highly cytocidal. Virus particles may form crystalline arrays in the cytoplasm of cells, which are recognized as acidophilic inclusions in histologic preparations.

Poliomyelitis

Acute anterior poliomyelitis (infantile paralysis, Heine-Medin disease) is an acute generalized disease caused by poliovirus infection. It is characterized by destruction of the motor cells in the spinal cord, brain, and brainstem and by the appearance of a flaccid paralysis of the muscles innervated by the affected neurons. Although the disease has probably occurred for many centuries, the first clear description was given by Jacob Heine in 1840, and the foundation of our knowledge of the epidemiology of the disease was laid by Medin in 1890. The studies of Landsteiner, Popper, Flexner, Lewis, and others in the first decade of the 20th century proved that the disease was caused by a virus.

Invasion of the nervous system occurs as a relatively late and infrequent manifestation. Orally ingested virus multiplies in the pharynx and ileum and probably in lymphoid tissue of the tonsils and Peyer patches. The virus then spreads to cervical and mesenteric lymph nodes and can be detected in the blood shortly thereafter. Viremia is accompanied by no symptoms or by a brief minor illness (fever, chills). It is still not definitely known how the virus gains access to the nervous system in paralytic cases. The most likely possibility is via direct spread from the blood at defective areas of the blood-brain barrier. Less likely is neural spread from the intestine or from neuromuscular junctions.

The virus has a predilection for the large motor cells, causing chromatolysis with acidophilic inclusions and necrosis of the cells. Degeneration of the neurons is accompanied by an inflammatory reaction in the adjacent meninges and the perivascular spaces and by secondary proliferation of the microglia. Recovery may occur in partially damaged cells, but the severely damaged cells are phagocytized and removed. The degenerative changes are most intense in the ventral horn cells and the motor cells in the medulla; however, neurons in the posterior horn, the posterior root ganglion, and elsewhere in the CNS are occasionally involved. Rarely, inflammation is also present in the white matter. Although the pathologic changes are most intense in the spinal cord, medulla, and motor areas of the cerebral cortex, any portion of the nervous system may be affected, including the midbrain, pons, cerebellum, basal ganglia, and nonmotor cerebral cortex.

Epidemiology

Acute anterior poliomyelitis is worldwide in distribution but is more prevalent in temperate climates. It may occur in sporadic, endemic, or epidemic form at any time of the year, but it is most common in late summer and early fall. Acute anterior poliomyelitis was formerly the most common form of viral infection of the nervous system. Before 1956, between 25,000 and 50,000 cases occurred annually in the United States.

Since the advent of effective vaccines, the incidence of the disease has dramatically decreased in the United States, as well as in other developed countries. In fact, in these countries, paralytic poliomyelitis is becoming a clinical rarity, except for isolated cases and small epidemics in areas where the population has not been vaccinated. In the United States, fewer than 10 cases of paralytic poliomyelitis occur each year, with most being vaccine-associated. A similar decrease has been reported in other countries in which vaccination has been practiced on a large scale. Paralytic poliomyelitis, however, is still a significant health problem in developing areas of the world. Worldwide in 1991, 12,992 cases of paralytic poliomyelitis were reported to the World Health Organization (WHO), but underreporting is significant. WHO studies have demonstrated that the actual number of cases is about 10 times the number reported.

Three antigenically distinct types of poliovirus have been defined. All three types can cause paralytic poliomyelitis or viral meningitis, but type I appears to be most often associated with paralytic disease.

The disease may occur at any age. It is rare before age 6 months. In the late 19th and early 20th centuries, poliomyelitis changed from an endemic to an epidemic disease. In the early epidemics, 90% of paralytic cases occurred in persons younger than 5 years. As epidemics recurred, there was a shift of paralytic cases to older

individuals, so that the majority of cases occurred in children older than 5 years and in teenagers. Paralysis was also seen more frequently in young adults.

Prophylaxis

Oral vaccination with live attenuated virus (oral poliovirus vaccine [OPV], Sabin) is effective in the prevention of paralytic infections. Antibody response depends on multiplication of attenuated virus in the gastrointestinal tract. Significant antibody levels develop more rapidly and persist longer than those that follow intramuscular immunization with formalized polioviruses (inactivated poliovirus vaccine [IPV], Salk). OPV is also capable of spreading and thus immunizing contacts of vaccinated individuals, but it can also cause vaccine-associated poliomyelitis. Because of this, the recommendations for vaccination in the United States have been changed to a sequential vaccination schedule with two doses of IPV followed by two doses of OPV.

Symptoms

The symptoms at the onset of poliomyelitis are similar to those of any acute infection (fever, chills, nausea, prostration). In about 25% of the patients, these initial symptoms subside in 36 to 48 hours, and patients are apparently well for 2 to 3 days until there is a secondary rise in temperature (dromedary type) accompanied by symptoms of meningeal irritation. In most patients, this second phase of the illness directly follows the first without any intervening period of freedom from symptoms. The headache increases in severity and muscle soreness appears, most commonly in the neck and back. Drowsiness or stupor occasionally develops, but patients are irritable and apprehensive, when aroused. Convulsions are occasionally seen at this stage in infants.

Paralysis, when it occurs, usually develops between the second and fifth day after the onset of signs of involvement of the nervous system, but it may be the initial symptom or, in rare instances, may be delayed for as long as 2 to 3 weeks. After the onset of paralysis, there may be extension of the motor loss for 3 to 5 days. Further progress of signs and symptoms rarely occurs after this time. The fever lasts for 4 to 7 days and subsides gradually. The temperature may return to normal before the paralysis develops or while the paralysis is advancing. Limb muscles are usually involved, but in severe cases respiratory and cardiac muscles may be affected. Acute cerebellar ataxia, isolated facial nerve palsies, and transverse myelitis have been observed in poliovirus-infected individuals.

Laboratory Data

Leukocytosis is present in the blood. CSF pressure may be increased. A CSF pleocytosis develops in the period before the onset of the paralysis. Initially, polymorphonuclear (PMN) leukocytes predominate, but a shift to lymphocytes occurs within several days. The CSF protein content is slightly elevated, except in patients with a severe degree of paralysis, when it may be elevated to 100 to 300 mg/dL and may persist for several weeks.

Diagnosis

Acute anterior poliomyelitis can be diagnosed without difficulty in most patients by the acute development of an asymmetric flaccid paralysis accompanied by the characteristic changes in the CSF. A presumptive diagnosis can be made in the preparalytic stage and in nonparalytic cases during an epidemic. The diagnosis can be suspected in patients who have not been vaccinated or have defects in their immune response. The diagnosis of poliovirus infection can be established by recovery of the virus from stool (usually lasts 2 to 3 weeks), throat washings (during the first week), or, rarely, from CSF or blood. Recovery of virus from the throat or feces requires the additional demonstration of a fourfold rise in the patient's antibody titer before a specific viral diagnosis can be made. With recent-generation magnetic resonance imaging (MRI) scanners, imaging studies may show localization of inflammation to the spinal cord anterior horns.

Prognosis

Fewer than 10% of patients die from the acute disease. Death is usually due to respiratory failure or pulmonary complications. The mortality rate is highest in the bulbar form of the disease, where it is often greater than 50%. The prognosis is poor when the paralysis is extensive or when there is a slow progress of paralysis with exacerbations and involvement of new muscles over a period of days. The prognosis with regard to return of function depends on age (infants and children have more recovery) and the extent of paralysis, as muscle groups only partially paralyzed are more likely to recover.

New symptoms develop in about 50% of patients 30 to 40 years after the acute poliomyelitis. These new symptoms have been collectively called the *postpolio syndrome*. In some of these patients, a slowly progressive weakness with atrophy and fasciculations develops, called *postpolio progressive muscular atrophy* (see [Chapter 118](#)).

Treatment

Treatment is essentially supportive. Attention should be given to respiration, swallowing, and bladder and bowel functions.

Treatment of patients with paralysis of respiratory muscles or bulbar involvement requires great care. They should be watched carefully for signs of respiratory embarrassment, and as soon as these become apparent, mechanical respiratory assistance should immediately be given. The development of anxiety in a previously calm patient is a serious warning of either cerebral anoxia or hypercarbia and may precede labored breathing or cyanosis.

Treatment in the convalescent stage and thereafter consists of physiotherapy, muscle reeducation, application of appropriate corrective appliances, and orthopedic surgery.

Coxsackievirus Infections

In 1948, Dalldorf and Sickles inoculated specimens obtained from patients with suspected poliomyelitis into the brains of newborn mice and discovered the coxsackieviruses. Two subgroups, A and B, can be distinguished by their effects on suckling mice. In mice, group A viruses cause myositis leading to flaccid paralysis and death. Group B viruses cause encephalitis, myocarditis, pancreatitis, and necrosis of brown fat; animals experience tremors, spasms, and paralysis before death. Twenty-three group A and six group B serotypes are currently recognized.

When involving the human nervous system, both group A and group B coxsackieviruses usually cause aseptic meningitis. When enteroviral meningitis occurs in infants, residual cognitive, language, and developmental abnormalities may occur. Occasionally, coxsackievirus infection causes encephalitis, and rarely paralytic disease or acute cerebellar ataxia are seen. Classic extraneural manifestations caused by group A coxsackieviruses are herpangina, hand-foot-and-mouth disease, and other rashes. Group B coxsackieviruses usually cause pericarditis, myocarditis, and epidemic myalgia (pleurodynia, Bornholm disease). They can also cause disseminated infection with severe encephalitis in newborns and may cause congenital anomalies if infection occurs in early pregnancy.

The symptoms and signs of meningeal involvement are similar to those that follow infection with other viruses that cause aseptic meningitis. The onset may be acute or subacute with fever, headache, malaise, nausea, and abdominal pain. Stiffness of the neck and vomiting usually begin 24 to 48 hours after the initial symptoms. There is a mild or moderate fever. Muscular paralysis, sensory disturbances, and reflex changes are rare. Paralysis, when present, is mild and transient. Meningeal symptoms occasionally occur in combination with myalgia, pleurodynia, or herpangina.

The CSF pressure is normal or slightly increased. There is a mild or moderate pleocytosis in the CSF, ranging from 25 to 250/mm³ with 10% to 50% PMN cells. The protein content is normal or slightly increased, and the sugar content is normal.

Diagnosis of coxsackievirus infection can be established only by recovering the virus from the feces, throat washings, or CSF and by demonstrating an increase in viral antibodies in the serum. Viral genetic amplification (PCR technique) has also been used for diagnosis. Meningitis due to a coxsackievirus cannot be distinguished from aseptic meningitis due to other viral agents, except by laboratory studies. It is differentiated from meningitis due to pyogenic bacteria and yeast by the relatively low cell count and the normal sugar content in the CSF. Differentiation must also be made from other diseases associated with lymphocytic pleocytosis in the CSF; these include tuberculous, fungal, or syphilitic meningitis; leptospirosis; Lyme disease; *Listeria monocytogenes*, *Mycoplasma*, or *Rickettsia* infections; toxoplasmosis; meningitis caused by other viruses; or parameningeal infections. Compared with these entities, coxsackievirus infections are more benign, and the CSF sugar content is normal.

Echovirus Infections

This group of enteroviruses was originally isolated in cell culture from the feces of apparently normal persons. They were considered “orphans” because they apparently did not cause disease. The designation “echo” is an acronym derived from the first letters of the term *enteric cytopathogenic human orphans*. Thirty-two serotypes are now recognized. Many strains cause hemagglutination of human type O erythrocytes.

The echoviruses cause gastroenteritis, macular exanthems, and upper respiratory infections. Echovirus-9 infections may cause a petechial rash that may be confused with meningococcemia. When the nervous system is infected, the syndrome of aseptic meningitis usually results.

The clinical picture of infection with the echoviruses is similar to that of other enterovirus infections. Children are more frequently affected than adults. The main features are fever, coryza, sore throat, vomiting, and diarrhea. A rubelliform rash is often present. Headache, neck stiffness, lethargy, and irritability indicate involvement of the nervous system. The disease usually runs a benign course that subsides in 1 or 2 weeks, but complications similar to those seen with coxsackievirus infections can occur.

Cerebellar ataxia has been reported in children as the result of echovirus infection. The onset of ataxia is acute; the course is benign with remission of symptoms within a few weeks. Pupil-sparing oculomotor nerve paralysis and other cranial nerve palsies have rarely been observed. Echoviruses can cause a persistent CNS infection in children with agammaglobulinemia; this is an echovirus-induced meningoencephalitis often associated with a dermatomyositis-like syndrome. It can be treated with immune globulin.

The CSF pleocytosis may vary from several hundred to a thousand or more cells per cubic millimeter, but it is usually less than 500/mm³. Early in the infection, there may be as many as 90% PMN leukocytes; within 48 hours, however, the response becomes completely mononuclear. The CSF protein content is normal or slightly elevated; the sugar content remains normal.

The echoviruses are commonly recovered from feces, throat swabs, and CSF. Virus typing is carried out by antibody testing. Viral genomic amplification has also been used for diagnosis. The differential diagnosis of echovirus meningitis is similar to that of coxsackievirus infections.

Infections with Enteroviruses 70 and 71 and Hepatitis A Virus

Newly recognized enteroviruses are now named as unclassified enteroviruses. Several of these new enteroviruses have caused CNS infections. Enterovirus 70 has caused epidemics of acute hemorrhagic conjunctivitis (AHC), which initially occurred in Africa and Asia. Neurologic abnormality occurs in about 1 in 10,000 or 1 in 15,000 cases of AHC, primarily in adults. Outbreaks of AHC have recently occurred in Latin America and the southeastern United States, but without any neurologic disease. The most common neurologic picture is a polioliike syndrome of flaccid, asymmetric, and proximal paralysis of the legs accompanied by severe radicular pain. Paralysis is permanent in more than 50% of patients. Isolated cranial nerve palsies (primary facial nerve), pyramidal tract signs, bladder paralysis, vertigo, and sensory loss have been reported. Because neurologic involvement usually occurs about 2 weeks after the onset of AHC, it may be difficult to isolate the virus at the time when neurologic signs are seen. Thus, diagnosis often depends on serologic studies. The neurologic disorder has rarely been seen without the preceding conjunctivitis.

Enterovirus 71 has been recognized as causing outbreaks of hand-foot-and-mouth disease. Upper respiratory infections and gastroenteritis also occur. Neurologic involvement may occur in up to 25% of patients, with children and teenagers primarily affected. Neurologic manifestations include aseptic meningitis, cerebellar ataxia, and various forms of poliomyelitis (flaccid monoparesis, bulbar polio). Most of these cases have occurred in Europe and Asia. Two cases of transient paralysis were seen in an outbreak in New York. Diagnosis can be made by virus isolation from throat, feces, or vesicles and by antibody studies.

Hepatitis A virus has apparently caused primarily encephalitis as a distinct entity, although hepatic encephalopathy is obviously more common. It has also been associated with transverse myelitis.

Arbovirus Infections

The arboviruses (*arthropod-borne*) are small, spherical, ether-sensitive (enveloped) viruses that contain RNA. More than 400 serologically distinct arboviruses are currently recognized. Although the term *arbovirus* is no longer an official taxonomic term, it is still useful to designate viruses transmitted by vectors. Arboviruses include the alphaviruses (formerly group A arboviruses), flaviviruses (formerly group B arboviruses), bunyaviruses, and some reoviruses ([Table 23.1](#)). The alphaviruses are one genus in the togavirus family; the other genus comprises the rubiviruses (rubella viruses). The equine encephalitides are caused by alphaviruses. The flavivirus family is composed of more than 60 viruses, including the viruses that cause yellow fever and St. Louis and Japanese encephalitides. The bunyaviruses include the California encephalitis group. The reovirus family includes the virus causing Colorado tick fever. St. Louis and California encephalitides are the most common arboviral encephalitides in the United States.

Arboviruses multiply in a blood-sucking arthropod vector. In their natural environment, they alternate between the invertebrate vector and a mammal. Mosquitoes and ticks are the most common vectors. Birds seem to be the principal natural hosts, but wild snakes and some rodents are probably a secondary reservoir. People and horses are usually incidental hosts, and human or horse infection in most arbovirus infections terminates the chain of infection (dead-end hosts). Approximately 80 arboviruses are known to cause human disease. The spectrum of disease produced is broad, ranging from hemorrhagic fevers (yellow fever) to arthralgia, rashes, and encephalitis.

Arboviruses are difficult to isolate in the laboratory. The virus may be recovered from blood during the early phases (2 to 4 days) of the illness. In nonfatal cases, the diagnosis usually depends on the demonstration of a fourfold rise in antibodies during the course of the illness. The virus may be isolated from the tissues at necropsy by the intracerebral inoculation of infant mice and susceptible tissue culture cells.

Arbovirus infection of the nervous system may result in viral meningitis but more frequently in moderate or severe encephalitis. Diseases due to arboviruses typically occur in late summer and early fall.

Equine Encephalitis

Three distinct types of equine encephalitis occur in the United States: eastern equine encephalitis (EEE), western equine encephalitis (WEE), and Venezuelan equine encephalitis (VEE). They are due to three serologically distinct alphaviruses. Infection with these viruses was thought to be limited to horses until 1932, when Meyer reported an unusual type of encephalitis in three men who were working in close contact with affected animals. The first cases in which EEE virus was recovered from human brain tissue were reported in Massachusetts in 1938 by Fothergill and coworkers. Many arboviruses take their name from the location in which they were first isolated; they are not confined, however, by specific geographic boundaries. EEE is usually localized to the Atlantic and Gulf coasts and the Great Lakes areas. Infrequently, cases of EEE have been reported in regions west of the Mississippi River, as well as in Central and South America and the Philippines. WEE virus infection is now known to occur in all parts of the United States, although most frequently in the western two-thirds of the country. VEE occurs in Central and South America and the southern half of the United States, but is a rare cause of encephalitis.

Pathology

In EEE, the brain is markedly congested, and there are widespread degenerative changes in nerve cells. The meninges and perivascular spaces of the brain are intensely infiltrated with PMN leukocytes and round cells. Focal vasculitic lesions, often with thrombus formation, may occur. Destruction of myelin is prominent only near the necrotic foci. Lesions are found in both the white and gray matter and are most intensive in the cerebrum and brainstem, but they may also be present in the cerebellum and spinal cord.

In contrast to EEE, the pathology of WEE is less intense, characterized by less inflammation, which is primarily mononuclear, and a paucity of nerve cell changes.

Incidence

Equine encephalitis is a rare human infection, tending to occur as isolated cases or in small epidemics. Epizootics in horses may precede the human cases by several weeks. Equine encephalitis mainly affects infants, children, and adults older than 50 years. Inapparent infection is common in all age groups.

Symptoms

Infection with the EEE virus begins with a short prodrome (approximately 5 days) of fever, headache, malaise, and nausea and vomiting. This is followed by the rapid onset of neurologic manifestations: confusion, drowsiness, stupor, or coma with convulsive seizures and neck stiffness. Cranial nerve palsies, hemiplegia, and other focal neurologic signs are common.

The symptoms of WEE and VEE are less severe. Onset is acute, with general malaise and headache occasionally followed by convulsions and nausea and vomiting. There is moderate fever and neck stiffness. The headaches increase in severity, and there is drowsiness, lethargy, or coma. Paresis and cranial nerve palsies may occur.

Laboratory Data

Leukocytosis may occur in the blood, especially in EEE; white blood cell counts as high as 35,000/mm³ have been reported. CSF changes are greatest in EEE, in which the pressure is always moderately or greatly increased. The CSF is cloudy or purulent, containing 500 to 3,000 cells/mm³. Initially, a predominance of PMN leukocytes usually occurs. The protein content is increased, but the sugar content is normal. With abatement of the acute stage, the cell count drops, and lymphocytes become the predominating cell type, although PMN cells persist as a significant fraction.

The CSF changes in the WEE and VEE are less severe. The pressure is usually normal, and the cellular increase is moderate, with counts varying from normal to 500/mm³, with mononuclear cells as the predominating cell type.

Diagnosis

Isolation of equine encephalitis viruses from blood and CSF is infrequent but should be attempted. Most arboviral infections are diagnosed serologically, with immunoglobulin M (IgM) assays available for rapid diagnosis. MRI may reveal focal lesions in the basal ganglia, thalami, and brainstem in about 50% of patients with EEE (Fig. 23.1). Computed tomography (CT) is less sensitive. A similar distribution of lesions on MRI has been seen in several other arboviral encephalitides (Japanese encephalitis, Central European tick-borne encephalitis).

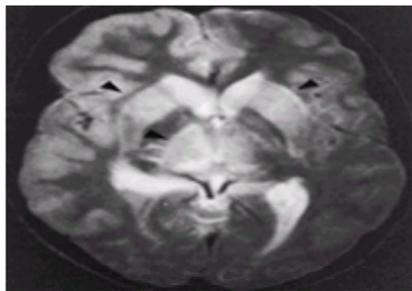

FIG. 23.1. Eastern equine encephalitis. Proton-density MR image 3 days after the onset of neurologic symptoms revealed large bilateral asymmetric lesions of the caudate, putamen, and thalamus (*arrowheads*). Less frequently, lesions can also be seen in the cortex, primarily in the medial temporal cortex and insula (not shown). (From Deresiewicz et al., 1997; with permission. Copyright © 1997 Massachusetts Medical Society. All rights reserved.)

Equine encephalitis must be differentiated from other acute infections of the CNS. These include postinfectious encephalomyelitis (exanthems, occurrence usually in the late fall and winter, abnormal MRI), advanced bacterial and tuberculous meningitis with parenchymal involvement (low CSF sugar content, positive cultures), brain abscess (abnormal imaging), parasitic encephalitis (detected by serology), and other viral infections. Differentiation from other viral encephalitides, except that caused by HSV, can be made only by isolation of the virus or by serologic tests.

Course and Prognosis

The average mortality rate in EEE is about 50%. The duration of the disease varies from less than 1 day in fulminating cases to more than 4 weeks in less severe cases. In patients who recover, sequelae such as mental deficiency, cranial nerve palsies, hemiplegia, aphasia, and convulsions are common. Children younger than 10 years are more likely to survive the acute infection, but they also have the greatest chance of being left with severe neurologic disability.

The fatality rate in WEE is about 10%. Sequelae among young infants are frequent and severe but are uncommon in adults. The mortality rate in VEE is less than 0.5%; nearly all deaths have occurred in young children.

Treatment

Treatment in the acute stage of equine encephalitis is entirely supportive. Vaccines against the causative viruses have been produced, but their use should be confined to laboratory workers and others who are subject to unusual exposure to the viruses. Vaccination in a large-scale community program is not indicated because of the low incidence of the disease. EEE and WEE have been prevented by controlling the vector by the use of large-scale insecticide spraying. However, the key to prevention is avoiding contact with mosquitoes: avoiding endemic areas, wearing appropriate clothing, and using mosquito repellents.

St. Louis Encephalitis

The first outbreak of acute encephalitis in which a virus was definitely established as the causative agent was an epidemic that occurred in St. Louis in 1933. This type of encephalitis probably existed in this area before 1933, as cases of encephalitis had occurred in St. Louis during the previous 14 years. Since 1933, repeated outbreaks have occurred in the United States with increasing frequency and widening geographic distribution.

The virus responsible for St. Louis encephalitis (SLE) is a mosquito-transmitted flavivirus. Epidemics follow two epidemiologic patterns: rural and urban. Rural epidemics tend to occur in the western United States. The rural cycle involves birds as the intermediate host, similar to WEE. Urban epidemics occur primarily in the midwestern United States, the Mississippi River Valley, and the eastern United States. Urban outbreaks can be abrupt and extensive because humans are the intermediate hosts. SLE primarily affects the elderly population. As with other arboviruses, disease in humans usually appears in midsummer to early fall.

Pathology

Grossly, there is a mild degree of vascular congestion and occasional petechial hemorrhages. Microscopic changes include a mild infiltration of the meninges and blood vessels of the brain with mononuclear cells; mononuclear, microglial, and glial cell accumulation in the parenchyma of both the gray and white matter; and degenerative changes in neurons. The nuclear masses of the thalamus and midbrain are more affected than the cortex.

Symptoms and Signs

Infection with the SLE virus usually results in inapparent infection. About 75% of patients with clinical manifestations have encephalitis; the others have aseptic meningitis or nonspecific illness. SLE is a disease of older adults. Encephalitic signs develop in almost all patients older than 40 years with symptoms. The onset of neurologic symptoms may be abrupt or may be preceded by a prodromal illness of 3 or 4 days' duration characterized by headache, myalgia, fever, sore throat, and nausea and vomiting. The headache increases in severity, and neck stiffness develops. Other common signs include pathologic reflexes, intention tremors, ataxia, and cranial nerve abnormalities. In more severe cases, there may be delirium, coma or stupor, focal neurologic signs, and, rarely, seizures, a poor prognostic sign.

Laboratory Data

A mild to moderate leukocytosis occurs in the blood. The CSF is usually abnormal, with a mild pleocytosis in most patients that averages approximately 100 cells/mm³. Cell counts as high as 500/mm³ or higher have been reported. Lymphocytes are the predominating cell type, although predominance of PMN cells may be found early in the disease. The sugar content is normal. Hyponatremia due to inappropriate secretion of antidiuretic hormone occurs in 25% to 33% of patients.

Diagnosis

The SLE virus is rarely isolated from the blood or CSF, and diagnosis depends on serologic testing. An IgM assay is available for rapid diagnosis. The differential diagnosis is similar to that of the equine encephalitides.

Course and Prognosis

The disease runs an acute course in most patients and usually results in death or recovery within 2 to 3 weeks. Mortality has varied from 2% to 20%. The most common sequelae of SLE are headaches, insomnia, easy fatigability, irritability, and memory loss, and these usually clear in several years. About 25% of survivors have permanent neurologic sequelae of cranial nerve palsies, hemiplegia, gait disorders, and aphasia.

Treatment

There is no specific treatment or a vaccine for SLE. Supportive care is essential. Vector control and avoidance of contact is preventive.

Japanese Encephalitis

Japanese encephalitis (JE) was first identified as a distinct disease after a large epidemic in 1924, although a form of the encephalitis had been recognized as early as 1871. The causative agent is a mosquito-transmitted flavivirus. Occurrence can be endemic (tropical areas) or epidemic (temperate zones). JE remains a major medical problem throughout Asia, with as many as 10,000 cases annually. The pathologic changes seen with JE are much more intense than those of SLE. In addition to infiltration of lymphocytes, monocytes, and microglial cells, severe neuronal necrosis occurs with neuronophagia in the entire cerebral cortex, basal ganglia, cerebellum, and spinal cord.

The clinical picture and laboratory findings in JE are similar to those of SLE. The disease is most common in children, and the mortality rate in some epidemics has been as high as 50%. This figure is undoubtedly too high because most mild cases are not admitted to hospitals. Severe neurologic residual effects and mental defects are common, especially in the young.

The diagnosis may be established by isolation of the virus from the blood, CSF, or cerebral tissue and by appropriate antibody tests. Neuroimaging studies have revealed findings similar to those reported for EEE (i.e., lesions of the thalami, basal ganglia, and brainstem).

There is no specific treatment. Vector control and vaccination are preventive. An inactivated-virus vaccine is routinely used in Japan, China, and Korea and is available for residents of the United States traveling to endemic or epidemic areas of Asia.

California (La Crosse) Encephalitis

Human neurologic disease associated with California encephalitis virus was first recognized in the early 1960s. Subsequently, La Crosse virus, also a member of the California virus serogroup, has been shown to cause most of these infections. Infection most frequently occurs in the upper midwestern United States, but it is found throughout the eastern half of the continental United States. These viruses are now known to be among the more important causes of encephalitis in the United States; fortunately, the encephalitis is usually mild. The California virus serogroup is now classified among the bunyaviruses, a group of enveloped viruses with segmented, helical, circular ribonucleoproteins.

The virus is transmitted by woodland mosquitoes. Its cycle involves small woodland animals, but not birds. Consequently, rural endemic rather than epidemic disease usually occurs. The disease occurs in the late summer and early fall, and nearly all patients are children. Infants younger than 1 year and adults are rarely affected. Headache, nausea and vomiting, changes in sensorium, meningeal irritation, and upper motor neuron signs have commonly been reported. Unlike in most other viral infections, the peripheral blood count is often quite elevated (20,000 to 30,000 cells/mm³). The CSF contains an increased number of lymphocytes and shows the other findings typical of viral meningitis or encephalitis. The diagnosis can be established by serologic studies.

The case fatality is low (less than 1%). Recovery usually occurs within 7 to 10 days. Emotional lability, learning difficulties, and recurrent seizures have been reported as sequelae.

Other Arbovirus Encephalitides

Colorado tick fever (CTF) is caused by a coltivirus (reovirus family) transmitted by wood ticks with small animals as intermediate hosts. CTF is confined to the geographic area of the tick in the Rocky Mountains. Infection often involves hikers, foresters, or vacationers in the spring and summer. Three to six days after a tick bite, an abrupt febrile illness develops with headache, myalgia, retroorbital pain, and photophobia. About 50% of patients have a biphasic fever pattern. Peripheral leukopenia and thrombocytopenia are common. Aseptic meningitis occurs in about 20% of patients. This is a benign disease; encephalitis and permanent sequelae are almost never seen. Diagnosis can readily be made by virus isolation from the blood or by serology.

Tick-borne encephalitis (TBE) viruses are closely related flaviviruses transmitted by wood ticks. Disease is seen primarily in the northern latitude woodlands of Siberia and Europe. The Siberian strains cause a severe encephalitis (Russian spring–summer encephalitis virus). The European and Scandinavian strains (Central European encephalitis) tend to cause a milder encephalitis that can present as a biphasic illness with recrudescence several weeks after the initial influenza-like illness. A case of TBE has been seen in Ohio after foreign tick exposure. Powassan virus, a member of the TBE complex, has been isolated from a few patients with severe encephalitis in the United States and Canada. A related virus, louping ill, causes a sporadic, mild encephalitis in the British Isles.

Other arboviruses that have occasionally caused epidemics of encephalitis include West Nile fever and Rift Valley fever in Africa and Murray Valley encephalitis in Australia.

Rubella

Rubella virus is not an arbovirus; it is now classified as a togavirus. It is an enveloped RNA virus that causes rubella (German measles), an exanthematous disease that can produce marked neurologic damage in the unborn child of a mother infected during pregnancy (congenital rubella syndrome [CRS]). Gregg, an Australian ophthalmologist, was the first to correlate the occurrence of congenital cataracts among newborn babies with maternal rubella infection during the first trimester of pregnancy. CRS is now known to produce a variety of defects, including deafness, mental retardation, and cardiac abnormalities. The frequency of congenital defects is highest in the first trimester of pregnancy and falls as gestation advances.

Rubella virus induces a chronic persistent infection in the fetus. For a long time after birth, infants may shed virus from the nasopharynx, eye, or CSF. Virus production continues despite the development of neutralizing and hemagglutinating antibodies by the infected child.

The lesions in the nervous system are those of a chronic leptomeningitis with infiltration of mononuclear cells, lymphocytes, and plasma cells. Small areas of necrosis and glial cell proliferation are seen in the basal ganglia, midbrain, pons, and spinal cord. Microscopic vasculitis and perivascular calcification may also occur.

The infant with rubella encephalitis is usually lethargic, hypotonic, or inactive at birth or within the first few days or weeks after birth. Within the next several months, restlessness, head retraction, opisthotonic posturing, and rigidity may develop. Seizures and a meningitis-like illness may occur. The anterior fontanelle is usually large; microcephaly occurs infrequently. The child may have other associated defects, such as deafness, cardiovascular anomalies, congestive heart failure, cataracts, thrombocytopenia, and areas of hyperpigmentation about the navel, forehead, and cheeks. Improvement of varying degrees may be noted after the first 6 to 12 months of life.

The CSF contains an increased number of cells (lymphocytes), as well as a moderately increased protein content. Rubella virus can be recovered from the CSF of approximately 25% of patients and may persist in the CSF for more than 1 year after birth.

Specific diagnosis can be made by recovery of the virus from throat swab, urine, CSF, leukocytes, bone marrow, or conjunctivae, or by serologic tests. A rubella-specific IgM serologic test can be used for diagnosis in the newborn.

Rubella virus also has caused postinfectious encephalomyelitis with acquired rubella and, rarely, a chronic or slow viral infection termed *progressive rubella panencephalitis* (see below).

The primary method of treatment is prevention of fetal infection. Live rubella virus vaccine should be given to all children between 1 year of age and puberty. Adolescent girls and nonpregnant women should be given vaccine if they are shown to be susceptible to rubella virus by serologic testing. Prevention has been highly effective. Between 1980 and 1996, fewer than 10 cases per year of CRS were reported.

Myxovirus Infections

Mumps Meningitis and Encephalomyelitis

Mumps is a disease caused by a paramyxovirus that has predilection for the salivary glands, mature gonads, pancreas, breast, and the nervous system. It is spread via respiratory droplets. There is only one serotype. Like other paramyxoviruses, mumps is an enveloped virus that develops from the cell surface by a budding process.

Clinical evidence of involvement of the nervous system occurs in the form of a mild meningitis or encephalitis in a small percentage of patients. Other neurologic complications of mumps include encephalomyelitis, myelitis, and peripheral neuritis. During mumps meningitis, virus replicates in choroidal and ependymal cells. It is not clear, however, if the encephalitis results from direct action of the virus or from immune-mediated demyelination (postinfectious encephalomyelitis).

Pathology

The pathology of mumps meningitis and encephalitis has not been clearly elucidated because of the low mortality rate. The pathologic changes are limited to infiltration of the meninges and cerebral blood vessels with lymphocytes and mononuclear cells. The morbid changes in patients with encephalomyelitis include perivenous demyelination with infiltration by lymphocytes and phagocytic microglia. Although pathologic changes are more prominent in white matter, focal areas of neuronal destruction can be seen.

Epidemiology

The incidence of neurologic complications of mumps varies greatly in different epidemics, ranging from a low of less than 1% to a high of about 70%. About two-thirds of patients with mumps parotitis have CSF pleocytosis, but only 50% of those with pleocytosis have CNS symptoms. Conversely, only about 50% of patients with CNS manifestations have parotitis.

Although the two sexes are equally susceptible to mumps, neurologic complications are three times more frequent in males. Children are commonly affected, but epidemics may occur in young adults living under community conditions, such as army camps. Most cases of mumps encephalitis in the United States appear to occur in the late winter and early spring.

Symptoms

In most patients, the symptoms of involvement of the nervous system are those of meningitis (i.e., headache, drowsiness, neck stiffness). These symptoms commonly appear 2 to 10 days after the onset of the parotitis; they occasionally precede the onset of swelling of the salivary glands. These symptoms are benign and disappear within a few days. When encephalitis occurs, it is usually mild.

Complications

Deafness is the most common sequel of mumps. Hearing loss, which is unilateral in more than 65% of patients, may develop gradually, or it may have an abrupt onset accompanied by vertigo and tinnitus. The deafness that follows mumps seems to be due to damage to the membranous labyrinth. Orchitis, oophoritis, pancreatitis, and thyroiditis may also occur. Severe myelitis, polyneuritis, encephalitis, optic neuritis, and other cranial nerve palsies may develop 7 to 15 days after the onset of parotitis, presumably from immune-mediated postinfectious encephalomyelitis.

A few cases of hydrocephalus have been reported in children who have had mumps virus infections. The hydrocephalus seems to be due to aqueductal stenosis induced by mumps virus, replication in aqueductal ependymal cells, and subsequent gliosis.

Laboratory Data

In mumps meningitis, the blood usually shows a relative lymphocytosis and a slight leukopenia. The CSF is under slightly increased pressure. The cell count is increased, usually in the range of 25 to 500 cells/mm³, but occasionally the counts may be as high as 3,000/mm³. Lymphocytes usually constitute 90% to 96% of the total, even in CSF with a high cell count, but PMN leukocytes occasionally predominate in the early stages. The degree of pleocytosis is not related to the severity of symptoms, and it may persist for 30 to 60 days. Inclusions of viral nucleocapsid-like material have been recognized by electron microscopic observation of CSF cells from patients with mumps meningitis. The protein content is normal or moderately increased, and mumps-specific oligoclonal immunoglobulin G (IgG) may be present. The sugar content is usually normal but may show a moderate reduction in 5% to 10% of patients. Mumps virus can be recovered from the CSF in a significant number of cases.

Diagnosis

Mumps meningitis is diagnosed on the basis of meningeal symptoms and CSF pleocytosis in a patient with mumps. In patients in whom neurologic symptoms develop during an epidemic of mumps and there is no evidence of involvement of the salivary glands, the diagnosis cannot be made with certainty unless the virus can be recovered from the CSF or there is a significant increase in antibodies in the serum. The presence of IgM antibody in the CSF is diagnostic. Virus can usually be recovered from the saliva, throat, urine, and CSF.

Mumps meningitis must be differentiated from other forms of meningitis, especially tuberculous and fungal, if the CSF glucose is low. A normal sugar content and the

absence of organisms in the CSF are important in excluding acute purulent, tuberculous, or fungal meningitis.

Treatment

Since licensure of the live attenuated mumps vaccine in 1967, the incidence of mumps has decreased to less than 5% of the prevaccine level. CNS complications (primarily meningitis) from the vaccine, if they occur at all, are rare.

Subacute Measles Encephalitis

Measles virus causes a wide spectrum of neurologic disease ranging from subclinical involvement and acute measles encephalitis (see "Postinfections Encephalomyelitis," below) within days after the onset of a measles exanthem to chronic subacute sclerosing panencephalitis (see below). Toxic encephalopathy and acute infantile hemiplegia rarely occur with measles infections, but these seem to be complications of severe febrile illnesses of childhood and are not specific syndromes caused by measles.

Subacute measles encephalitis (measles inclusion body encephalitis, immunosuppressive measles encephalitis) occurs as an opportunistic infection in immunosuppressed or immunodeficient patients. Most cases have occurred in children, but a few have occurred in adults. Several cases have been reported in patients with no obvious immune defects. A history of measles exposure 1 to 6 months before the onset of neurologic disease can usually be obtained. The disease is characterized by generalized and focal seizures, including epilepsy partialis continua, occasional focal deficits, and a progressive deterioration of mental function leading to coma and death in several weeks to 4 or 5 months. Routine CSF tests are normal. Diagnosis may be difficult because there may not be a history of a rash or even obvious exposure. At the time of presentation, measles antibody may not be present in the serum or CSF. Brain biopsy may be required. Pathology reveals numerous inclusions in neurons and glia with microglial activation, but minimal perivascular inflammation. The role of postexposure immunoglobulin prophylaxis is unclear. In several patients, intravenous ribavirin treatment has resulted in improvement.

Rhabdovirus Infection

Rabies

Rabies (hydrophobia, lyssa, rage) is an acute viral disease of the CNS that is transmitted to humans by the bite of an infected (rabid) animal. It is characterized by a variable incubation period, restlessness, hyperesthesia, convulsions, laryngeal spasms, widespread paralysis, and almost invariably death.

Etiology

Rabies virus is an enveloped bullet-shaped virus that contains single-stranded RNA. Because of its characteristic morphology, rabies has been classified among the *rhabdo* (rod-shaped) viruses. The virus appears capable of infecting every warm-blooded animal. Rabies virus is present in the saliva of infected animals and is transmitted to humans by bites or abrasions of the skin. The bite of a rabid dog or exposure to bats is the usual circumstance, but the disease may be transmitted by cats, wolves, foxes, raccoons, skunks, and other domestic or wild animals. After inoculation, the virus replicates in muscle cells and then travels to the CNS by way of both sensory and motor nerves by axonal transport. After CNS invasion, dissemination of virus is rapid, with early selective involvement of limbic system neurons.

Several cases of airborne transmission of rabies have occurred in spelunkers of bat-infested caves and in laboratory workers. Unusual human-to-human transmission has occurred in two patients who were recipients of corneal transplants.

The incubation period usually varies between 1 and 3 months, with the extremes of 10 days and more than 1 year. In general, the incubation period is directly related to the severity of the bite or bites and their location. The period is shortest when the wound is on the face and longest when on the leg.

Pathology

The pathology of rabies is that of a generalized encephalitis and myelitis. There is perivascular infiltration of the entire CNS with lymphocytes and, to a lesser extent, PMN leukocytes and plasma cells. The perivascular infiltration is usually mild and may be focal or diffuse. Diffuse degenerative changes occur in the neurons. Pathognomonic of the disease is the presence of cytoplasmic eosinophilic inclusions, with central basophilic granules that are found in neurons (Negri bodies) ([Fig. 23.2](#)). These are usually found in pyramidal cells of the hippocampus and cerebellar Purkinje cells, but they may be seen in neurons of the cortex and other regions of the CNS, as well as in the spinal ganglia. These inclusions contain rabies virus antigen, as demonstrated by immunofluorescence. Rabies virus nucleocapsids have been found in electron microscopic studies of the inclusions. These inclusion bodies are occasionally absent. There is proliferation of microglia with the formation of rod cells, which may be collected into small nodules (Babés nodules). In cases with a long incubation period, the degenerative changes in neurons may be quite severe with little or no inflammatory reaction.

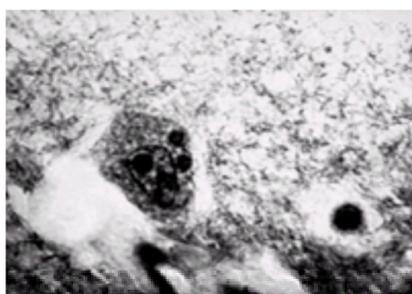

FIG. 23.2. Rabies. Inclusion bodies (Negri bodies) in cytoplasm of a ganglion cell of cerebral cortex.

Incidence

The incidence of rabies is inversely proportional to the control of rabid animals. Wildlife rabies has become an increasingly serious problem in the United States during the 1990s. However, the disease in wildlife is almost nonexistent in Great Britain, where strict animal regulations are enforced. Human rabies is a clinical rarity in the United States and most of the countries of central Europe, but it is still common in southeastern Europe and Asia. There have been 36 cases of human rabies in the United States from 1980 through 1997. About 50% of the cases were imported.

The incidence of the disease in individuals who have been bitten by rabid dogs is low (15%), but it is high (40%) when the bite is inflicted by a rabid wolf. The incidence is highest when the wounds are severe and near the head. It is low when the bite is inflicted through clothing, which cleans some or most of the infecting saliva from the teeth.

Symptoms

Onset is denoted by pain or numbness in the region of the bite in about 50% of patients. Other initial symptoms include fever, apathy, drowsiness, headache, and anorexia. This period of lethargy passes rapidly into a state of excitability in which all external stimuli are apt to cause localized twitchings or generalized convulsions. There may be delirium with hallucinations and bizarre behavior (thrashing, biting, severe anxiety). A profuse flow of saliva occurs; spasmodic contractions of the pharynx and larynx are precipitated by any attempt to consume liquid or solid food. As a result, the patient violently refuses to accept any liquids, hence, the name hydrophobia. The body temperature is usually elevated and may reach 105° to 107°F (40.6° to 41.7°C) in the terminal stages. The stage of hyperirritability gradually

passes into a state of generalized paralysis and coma. Death results from paralysis of respiration.

The disease occasionally begins with paralysis (paralytic form or dumb rabies) without convulsive phenomena or laryngeal spasm. The paralysis is a flaccid type and may start in one limb and spread rapidly to involve the others. The paralysis is more often symmetric than asymmetric. Symptoms and signs of a transverse myelitis may develop.

Laboratory Data

Leukocytosis occurs in the blood, and albumin may be present in the urine. The CSF is under normal pressure, and a lymphocytic pleocytosis is present, varying from five to several hundred cells per cubic millimeter in only about 50% of patients. The protein content is usually increased.

Diagnosis

Rabies is often diagnosed from the appearance of the characteristic symptoms after the bite of a rabid animal. The diagnosis can occasionally be made by fluorescent antibody staining of corneal smears or skin biopsies from the back of the neck, although both false-negative and false-positive results occur. Serum and CSF should also be tested for rabies antibodies. However, negative results for these tests do not rule out the possibility of rabies. The presence of rabies antibodies in the CSF is diagnostic. Virus isolation from the saliva, throat, tears, and CSF should also be attempted, although this is rarely successful. With the recent introduction of PCR techniques, virus detection in these specimens appears to be more successful. The only sure way of making the diagnosis while the patient is alive is by brain biopsy. The differential diagnosis includes all forms of encephalitis and, for the paralytic form of rabies, those viruses causing lower motor neuron paralysis.

Course and Prognosis

The disease is almost always fatal and usually runs its course in 2 to 10 days. Death within 24 hours of the onset of symptoms has been reported. Several cases with recovery have been reported.

Treatment

There is no specific antiviral therapy. Treatment during the encephalitic phase is supportive and, as noted, rarely successful. Specific treatment is entirely prophylactic and includes both passive antibody and vaccine. Passive immunization is by use of human rabies immune globulin. Immune globulin is infiltrated into the wound and given intramuscularly. A full course of active immunization with rabies vaccine should be given.

Arenavirus Infections

Lymphocytic Choriomeningitis

Lymphocytic choriomeningitis (LCM) is a relatively benign viral infection of the meninges and CNS. The clinical features of the disease were described by Wallgren in 1925 (under the term *aseptic meningitis*). The disease is of historic importance because it was the first in which a virus was proved to be the cause of a benign meningitis with a predominance of lymphocytes in the CSF. The role of the virus in human disease was established by Rivers and Scott in 1935, when they isolated it from the CSF of two patients with the clinical syndrome described by Wallgren.

LCM virus is an enveloped RNA virus. It causes less than 0.5% of cases of viral meningitis. Neurologic disease develops in only about 15% of those infected. Mice are the major reservoir of the virus and are implicated as the intermediate host. Both pet and laboratory hamsters have also been a source of infection. Ingestion of food contaminated by animal excreta and wound exposure to contaminated dirt are thought to be the modes of transmission. Human-to-human transmission does not occur. The disease is most common in the winter, when mice move indoors.

Onset of the infection is characterized by fever, headache, malaise, myalgia, and symptoms of upper respiratory infection or pneumonia. In a few patients, meningeal symptoms develop within 1 week after the onset. Occasionally, there is a remission in the prodromal symptoms, and the patient is apparently in good health when meningeal symptoms develop. Severe headache, nausea, and vomiting mark the beginning of neurologic involvement, most often aseptic meningitis. The temperature is moderately elevated (99° to 104°F [37.2° to 40.0°C]). The usual signs of meningitis (stiff neck, Kernig and Brudzinski signs) are present. The parenchyma is occasionally involved (encephalitic or meningoencephalitic forms), but good restoration of function usually occurs. Fewer than 12 deaths have been reported.

In the early influenza-like stages, leukopenia and thrombocytopenia may be seen. Later, the leukocyte count may be elevated with a predominance of PMN leukocytes. The CSF findings are similar to those of other viral causes of meningitis.

A definitive viral diagnosis may be made by recovery of the virus from blood or CSF, but in most patients the diagnosis is made by serology. The differential diagnosis is similar to that of enterovirus infection, the most common cause of viral meningitis.

The duration of the meningeal symptoms varies from 1 to 4 weeks with an average of 3 weeks. The mortality rate is low, and complete recovery is the rule, except in the rare patients with encephalitis in whom residuals of focal lesions in the brain or spinal cord may be present. There is no specific treatment.

Other Arenavirus Infections

Junin (Argentinian hemorrhagic fever) and Machupo (Bolivian hemorrhagic fever) viruses and Lassa fever virus of Africa cause severe hemorrhagic fevers. Although hemorrhage and shock are the usual causes of death from these severe systemic infections, neurologic involvement is not unusual.

Adenovirus Infections

Adenoviruses are nonenveloped (ether-resistant), icosahedral DNA containing viruses of which there are more than 30 serotypes. These viruses were not discovered until 1953 when they were isolated from tissue culture of surgically removed tonsils and adenoids, thus the name. Adenoviruses can be spread by both respiratory and gastrointestinal routes and cause a variety of clinical syndromes. Respiratory infection is most often seen, manifested by coryza, pharyngitis, and, at times, pneumonia. Pharyngoconjunctival fever, epidemic keratoconjunctivitis, pertussis-like syndrome, and hemorrhagic cystitis are other manifestations. Most infections occur in children; about 50% of these infections are asymptomatic. Epidemics of respiratory diseases have occurred among military personnel. Opportunistic infections have occurred in both adults and children.

Neurologic involvement has occurred mostly in children as an encephalitis or meningoencephalitis and is quite rare. Only a few pathologic studies have been performed, and the encephalitis appears to be of the primary type with virus invasion of the brain. Histologic changes include perivascular cuffing and mononuclear cell parenchyma infiltrates, but in some patients, little or no inflammation is seen. Virus has been isolated from the brain and CSF in several patients. The encephalitis is usually of moderate to severe intensity with meningism, lethargy, confusion, coma, and convulsions. Ataxia has also been reported. Death occurs in up to 30% of patients. CSF pleocytosis often, but not always, occurs and can be PMN or mononuclear. The protein content may be normal or elevated. Diagnosis can be made by serology or by isolation of virus from the CSF, throat, respiratory secretions, and feces. There is no specific treatment.

Herpesvirus Infections

The herpesvirus group is composed of DNA-containing viruses that have a lipid envelope and multiply in the cell nucleus. Members of this group share the common feature of establishing latent infections. Herpesviruses may remain quiescent for long periods of time, being demonstrable only sporadically or not at all until a stimulus triggers reactivated infection. Within cells, accumulations of virus particles can often be recognized in the nucleus in the form of acidophilic inclusion bodies. There are at present eight recognized members of the human herpesvirus family: herpes simplex virus (HSV) types 1 and 2, varicella-zoster virus (VZV), Epstein-Barr virus (EBV), cytomegalovirus (CMV), human herpesvirus 6 (HHV-6), HHV-7, and HHV-8, also known as Kaposi sarcoma herpesvirus. All of these viruses are capable of causing neurologic disease, but only a few cases have been reported in association with HHV-7 and HHV-8.

Herpes Simplex Encephalitis

Encephalitis caused by HSV is the single most important cause of fatal sporadic encephalitis in the United States. Early diagnosis is crucial because there is effective antiviral treatment.

Etiology

Two antigenic types of HSV are distinguished by serologic testing. Type 1 strains (HSV-1) are responsible for almost all cases of HSV encephalitis in adults and cause oral herpes. Type 2 strains (HSV-2) cause genital disease. In the neonatal period, HSV-2 encephalitis occurs as part of a disseminated infection or as localized disease acquired during delivery. In adults, HSV-2 is spread by venereal transmission and causes aseptic meningitis.

Pathogenesis

HSV-1 is transmitted by respiratory or salivary contact. Primary infection usually occurs in childhood or adolescence. It is usually subclinical or may present as stomatitis, pharyngitis, or respiratory disease. About 50% of the population has antibody to HSV-1 by age 15 years, whereas 50% to 90% of adults have antibody, depending on socioeconomic status. HSV-1 encephalitis can occur at any age, but more than 50% of cases occur in patients older than 20 years. This finding suggests that encephalitis most often occurs from endogenous reactivation of virus rather than from primary infection. Neurologic involvement is a rare complication of reactivation. During the primary infection, virus becomes latent in the trigeminal ganglia. Years later, nonspecific stimuli cause reactivation, which is usually manifested as herpes labialis (cold sores). Presumably, virus can reach the brain through branches of the trigeminal nerve to the basal meninges, resulting in localization of the encephalitis to the temporal and orbital frontal lobes. Alternatively, serologic studies suggest that about 25% of cases of HSV-1 encephalitis occur as part of a primary infection. Experimental studies indicate that this could occur by spread of virus across the olfactory bulbs to the orbital frontal lobes and subsequently the temporal lobes. The encephalitis is sporadic without seasonal variations. HSV-1 encephalitis rarely occurs as an opportunistic infection in immunocompromised hosts.

Except when infantile infection occurs at delivery, HSV-2 is spread by sexual contact. Thus, primary infection usually occurs during the late teenage or early adult years. As noted previously, HSV-2 causes aseptic meningitis in adults, which probably occurs as part of the primary infection. As with HSV-1, opportunistic infections may also occur in immunocompromised patients.

Pathology

In fatal cases, intense meningitis and widespread destructive changes occur in the brain parenchyma. Necrotic, inflammatory, or hemorrhagic lesions may be found. These lesions are maximal, most often in the frontal and temporal lobes. There is often an unusual degree of cerebral edema accompanying the necrotic lesions. Eosinophilic intranuclear inclusion bodies (Cowdry type A inclusions) are present in neurons. These inclusions containing herpesvirus particles are recognized on electron microscopic examination.

Symptoms and Signs

The most common early manifestations are fever, headache, and altered consciousness and personality (see [Table 23.3](#)). Onset is most often abrupt and may be ushered in by major motor or focal seizures. The encephalitis may evolve more slowly, however, with aphasia or mental changes preceding more severe neurologic signs. Most patients have a temperature between 101° and 104°F (38.4° and 40.0°C) at the time of admission. Nuchal rigidity or other signs of meningeal irritation are often found. Mental deficits include confusion and personality changes varying from withdrawal to agitation with hallucinations. A progressive course ensues within hours to several days, with an increasing impairment of consciousness and the development of focal neurologic signs. Rarely, the course may be subacute or chronic, lasting several months. Focal signs, such as hemiplegia, hemisensory loss, focal seizures, and ataxia, are considered distinguishing features of herpes encephalitis but are seen in less than 50% of affected patients on initial examination. Herpetic skin lesions are seen in only a few patients but are also seen with other diseases. A history of cold sores is not helpful because the incidence is similar to that of the general population.

	NIH Collaborative Study*	Swedish Study*
Symptoms		
Altered consciousness	97% (108/112)	100% (25/25)
Fever	90% (101/112)	100% (25/25)

TABLE 23.3. MANIFESTATIONS OF HERPES SIMPLEX ENCEPHALITIS AT PRESENTATION

Laboratory Data

There is a moderate leukocytosis in the blood. The CSF pressure may be moderately or greatly increased. Pleocytosis in the CSF varies from less than 10 to 1,000 cells/mm³; lymphocytes usually predominate, but occasionally PMN leukocytes may predominate early in the infection, followed by a shift to lymphocytes. Red blood cells are frequently seen, but their presence or absence is not diagnostic. The CSF sugar content is usually normal but may be low. Virus is rarely recovered from the CSF. In 5% to 10% of patients, the initial CSF examination is normal.

The electroencephalogram (EEG) and MRI are the most likely diagnostic studies to be abnormal at onset and during the first week of infection. The EEG is usually abnormal (about 80% in biopsy-proven cases) with diffuse slowing or focal changes over temporal areas; periodic complexes against a slow-wave background may be seen. CT may demonstrate low-density abnormality, mass effect, or linear contrast enhancement in more than 90% of patients, but it is often entirely normal during the first week of disease ([Fig. 23.3](#)). Thus, CT cannot be relied on for early diagnosis. MRI often reveals focality during the first week of disease when the CT scan is normal ([Fig. 23.4](#)).

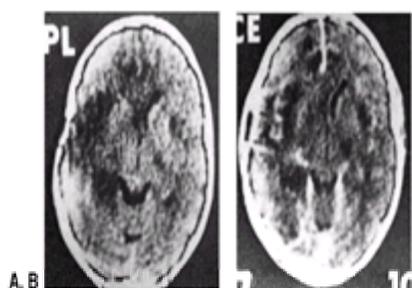

FIG. 23.3. Herpes simplex encephalitis. **A:** Axial CT on day 10 shows a low-density lesion in the right temporal and basal frontal lobes. **B:** Corresponding contrast-enhanced CT shows gyral enhancement in the sylvian fissure and insular regions, which is greater on the right. An abnormal CT is not usually seen until day

6 or 7 after the onset of manifestations. Eventually, a majority of scans show gyral enhancement in the sylvian fissure area. These findings should raise the suspicion of an underlying infectious lesion such as herpes, early infarction from emboli or vasculitis, or metastatic tumors. (From Davis JM, et al. Computed tomography of herpes simplex encephalitis with clinicopathological correlation. *Radiology* 1978;129:409–417; with permission.)

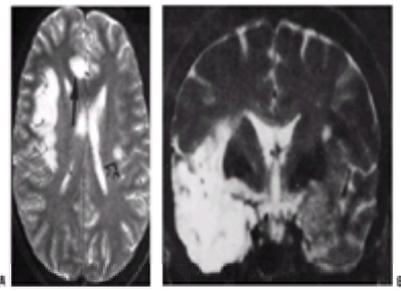

FIG. 23.4. Herpes simplex encephalitis. **A:** T2-weighted axial MRI reveals high signal intensity in the right insular cortex, medial right frontal cortex (*solid arrow*), and left insular cortex (*open arrow*). (From Runge VM. *Magnetic resonance imaging of the brain*. Philadelphia: JB Lippincott Co, 1994:190; with permission.) **B:** T2-weighted coronal MRI shows increased signal in the left temporal lobe and early involvement of the right side. (From Schroth et al., 1987; with permission.) An abnormal MR image is usually seen by day 1 or 2 after the onset of manifestations. Coronal images are the most useful for detecting the herpes simplex lesions.

Diagnosis

Because HSV encephalitis has a high mortality rate and the outcome of therapy is affected by the patient's level of consciousness and neurologic deficits, diagnostic measures leading to a presumptive diagnosis should be initiated as soon as possible. Presumptive diagnosis for treatment can be made based on clinical, CT, CSF, EEG, and MRI findings. Definitive diagnosis can be established only by recovery of virus from the CSF (rare) or brain, demonstration of viral DNA in the CSF or brain by PCR amplification, or the finding of viral antigen in the brain. Because patients may show a rise in antibody titer with recurrent HSV cutaneous lesions or with inapparent infection, a fourfold rise in the serum antibody titer to herpesvirus may occur in patients with encephalitis from other causes. The appearance of herpes antibodies in the CSF is a useful retrospective diagnostic test, but these antibodies occur too late in the disease to aid in therapy.

The differential diagnosis of HSV-1 encephalitis includes other viral and postinfectious encephalitides; bacterial, fungal, and parasitic infections; and tumors. Brain abscess is often the most difficult diagnosis to exclude. Before the advent of MRI, about 25% of biopsy-negative patients had another treatable disease.

Prognosis and Treatment

Without treatment, the disease is fatal in about 70% to 80% of patients, and patients who survive the acute disease are usually left with severe neurologic residuals. Measures to decrease life-threatening brain edema, including the administration of corticosteroids, are indicated. Vidarabine (Vira-A), a DNA polymerase inhibitor, has been demonstrated to decrease mortality to 44% at 6 months compared to 70% for patients receiving placebo. Subsequently, acyclovir was demonstrated to be more efficacious than vidarabine in two controlled trials. In the National Institute of Allergy and Infectious Disease study, acyclovir reduced mortality to 28% compared to 55% for vidarabine at 18 months. It selectively inhibits virus-specific polymerase, has less toxicity than vidarabine, and is now the drug of choice. Outcome depends on patient age, level of consciousness, and the rapidity with which treatment is instituted. After presumptive diagnosis, acyclovir treatment should be instituted even if MRI cannot be performed until the next day. If deterioration in the clinical course occurs over the next 48 to 72 hours, brain biopsy is indicated. Because relapses have occurred after a 10-day treatment regimen, a 14-day course is now recommended.

Herpes Zoster

Herpes zoster (shingles) is a viral disease that produces inflammatory lesions in the posterior root ganglia and is characterized clinically by pain and a skin eruption in the distribution of the affected ganglia. Involvement of motor roots or the CNS occurs in a small percentage of patients.

Etiology

The virus of herpes zoster is identical to VZV, the causative agent of chickenpox (varicella). VZV is a large, enveloped, DNA-containing virus that has the same structure as that of other herpesviruses. Children can catch chickenpox from exposure to adults with shingles, but adults are subject to herpes zoster only if they have had chickenpox earlier in life. The CNS complications (acute cerebellar ataxia, encephalitis, myelitis, meningitis) of varicella are thought to occur by a postinfectious autoimmune mechanism (see "[Acute Disseminated Encephalomyelitis](#)" below), although direct viral invasion may occur less frequently. Epidemiologic considerations led Hope-Simpson to speculate that zoster infection is a reactivation of latent VZV originally acquired in a childhood attack of chickenpox. Herpes zoster frequently occurs in connection with systemic infections, immunosuppressive therapy, and localized lesions of the spine or nerve roots (e.g., acute meningitides, tuberculosis, Hodgkin disease, metastatic carcinoma, trauma to the spine).

Pathology

Although symptoms are usually confined to the distribution of one or two sensory roots, the pathologic changes are usually more widespread. The affected ganglia of the spinal or cranial nerve roots are swollen and inflamed. The inflammatory reaction is chiefly of a lymphocytic nature, but a few PMN leukocytes or plasma cells may also be present. The inflammatory process commonly extends to the meninges and into the root entry zone (posterior poliomyelitis). Not infrequently, some inflammatory reaction occurs in the ventral horn and in the perivascular space of the white matter of the spinal cord. The pathologic changes in the ganglia of the cranial nerves and in the brainstem are similar to those in the spinal root and spinal cord.

Incidence

Herpes zoster is a relatively common disease with an incidence that varies from 1 to 5 cases per 1,000 people each year. Rates are higher in patients with malignancies and in those receiving immunosuppressive therapy. Symptoms of involvement of the nervous system, with the exception of pain, are rare, only occurring in about 10% of patients. Zoster is more common in middle or later life.

Symptoms and Signs

The initial symptom is usually a neuralgic pain or dysesthesia in the distribution of the affected root. The pain is followed in 3 to 4 days by reddening of the skin and the appearance of clusters of vesicles in part of the area supplied by the affected roots. These vesicles, which contain clear fluid, may be discrete or may coalesce. Within 10 days to 2 weeks, the vesicles are covered with a scab, which after desquamation leaves a pigmented scar. These scars are usually replaced by normally colored skin in the ensuing months. Permanent scarring may occur if there is ulceration or secondary infection of the vesicles. Coincidental to the eruption is adenopathy that is usually painless.

Herpes zoster is primarily an infection of the spinal ganglia, but the cranial ganglia are affected in about 20% of patients. The thoracic, lumbar, cervical, and sacral segments are involved in descending order of frequency. Involvement is almost always unilateral.

Among the less common symptoms are impairment of cutaneous sensation and muscle weakness in the distribution of the affected root, malaise, fever, headache, neck stiffness, and confusion. The latter symptoms indicate involvement of the meninges. Involvement of the cervical or lumbar segments may be accompanied by

frequent, however. CNS involvement in immunocompromised patients is often asymptomatic, although fatal encephalitis may occur. The encephalitis has a subacute or chronic course and is clinically indistinguishable from HIV encephalitis (HIV dementia). MRI demonstrates either diffuse or focal white matter abnormalities in about 25% of patients. CMV infection has also been implicated as a cause of both a subacute polyradiculomyelopathy and a multifocal neuropathy that have been seen only in AIDS patients. The polyradiculomyelopathy has a subacute onset of leg weakness and numbness leading to a flaccid paraplegia.

For cytomegalic inclusion body disease, CMV can be recovered from urine, saliva, or liver biopsy specimens. Complement-fixation and neutralization tests are available. A presumptive diagnosis can be made by finding typical cytomegalic cells in stained preparations of urinary sediment or saliva.

In adult infections, virus may be cultured from extraneural sites. Antibody testing is usually not helpful in immunodeficient patients. CMV cannot be cultured from the CSF; PCR amplification is the best microbiologic test. In polyradiculomyelopathy, PMN cells are often seen in the CSF, and there may be meningeal enhancement on MRI.

Both ganciclovir and foscarnet have been reported to be beneficial for some postnatally acquired infections. Recent case reports have noted successful treatment with cidofovir.

Epstein-Barr Virus Infection

Infectious mononucleosis (glandular fever) is a systemic disease of viral origin with involvement of the lymph nodes, spleen, liver, skin, and, occasionally, the CNS. It occurs sporadically and in small epidemics. It is most common in children and young adults. The usual symptoms and signs are headache, malaise, sore throat, fever, enlargement of the lymph nodes in the cervical region, occasionally enlargement of the spleen, and changes in the blood. Unusual manifestations include a cutaneous rash, jaundice, and symptoms of involvement of the nervous system.

Although neurologic complications rank first as a cause of death, there have been few autopsy studies of the brain in fatal cases of infectious mononucleosis. Acute cortical inflammation similar to that seen in other viral infections has been observed. Atypical cells, probably lymphocytes, have been found in the inflammatory exudate.

The exact incidence of involvement of the nervous system is unknown, but it is probably less than 1%. A lymphocytic pleocytosis in the CSF may be found in the absence of any neurologic symptoms or signs. Severe headache and neck stiffness may be the initial or only symptoms of cerebral involvement (aseptic meningitis). Signs of encephalitis (delirium, convulsions, coma, and focal deficits) are rare manifestations. Optic neuritis, paralysis of the facial and other cranial nerves, acute autonomic neuropathy, infectious polyneuritis (Guillain-Barré syndrome), and transverse myelitis have been reported in a few patients. Acute cerebellar ataxia has also been associated with infectious mononucleosis.

CNS manifestations may appear early in the course of the disease in the absence of any other findings, but usually occur 1 to 3 weeks after onset. The prognosis for EBV encephalitis is excellent with few fatalities and minimal residua.

In the laboratory examination, the important findings are leukocytosis in the blood with an increase in lymphocytes and the appearance of abnormal mononuclear cells (atypical lymphocytes). Liver function tests are often abnormal, and heterophil antibody is present in 90% of patients. With involvement of the meninges, the CSF shows a lymphocytic pleocytosis (10 to 600 cells/mm³) with or without a slight increase in protein content. The sugar content is normal, and CSF serologic tests for syphilis are negative. False-positive tests for syphilis are occasionally obtained on the serum.

The diagnosis is established by the appearance of neurologic symptoms in patients with other manifestations of the disease. The differential diagnosis includes other viral diseases that cause a lymphocytic meningeal reaction. The diagnosis can be made by a study of the blood, the heterophil antibody reaction, and measurement of specific antibodies to EBV antigens. At times, EBV can be isolated from the oropharynx. MRI abnormalities have been reported, with both gray and white matter lesions, in about 25% of patients.

There is no specific therapy. Treatment with steroids may be indicated in certain patients with severe pharyngotonsillitis or other complications.

Human Herpesvirus-6 Infection

HHV-6 was first isolated from AIDS patients in 1986. Two years later it was shown to be the etiologic agent for roseola infantum (exanthema subitum, sixth disease). HHV-6 has also been found to cause opportunistic CNS disease in immunocompromised individuals.

Roseola is an acute, self-limited disease of infants and children. It is caused by an HHV-6 primary infection. It begins with abrupt onset of high fever, lasting 3 to 4 days. Febrile convulsions commonly occur with a high fever. As the temperature rapidly falls, a transient maculopapular rash appears on the neck and trunk. The rash fades in 1 to 3 days. Other physical findings are minimal but include mild injection of the pharynx and tympanic membranes and postoccipital and postauricular lymphadenopathy.

The most common CNS complication of roseola is febrile seizures, which occur in up to one-third of patients. Several studies suggest that recurrent seizures may develop in a small percentage of these patients. Meningoencephalitis has also occurred as a complication of roseola. Manifestations include persistent fever, a depressed level of consciousness, and seizures. The prognosis is variable. There is usually a mild mononuclear pleocytosis in the CSF. Less frequently, encephalopathy (no CSF pleocytosis) and demyelination have been reported.

Recurrent HHV-6 infections have been associated with a range of illnesses (pneumonia, bone marrow suppression, possibly lymphoma and encephalitis) in immunocompromised patients. The encephalitis occurring in these patients is usually more severe than that seen during roseola, and is more likely to result in death.

Diagnosis

During roseola, initially the peripheral white blood cell count may be slightly elevated, but with disease progression, leukopenia is invariably present. This finding, along with the characteristic presentation and course, makes a presumptive diagnosis of roseola. Diagnosis is confirmed by isolation of virus (throat, saliva, blood) and seroconversion. Since HHV-6 appears to be latent in the brain, it is not clear what role CSF PCR amplification and CSF antibody assays will have in diagnosis. The diagnosis of reactivated infection is also confirmed by virus isolation and, at times, with a concomitant fourfold rise in IgG titer.

Treatment

For roseola, antipyretics are important for controlling the fever, which should decrease the incidence of febrile seizures. Anticonvulsants may be needed for recurrent seizures. Systemic antiviral agents should be used for CNS or systemic disease occurrence with roseola or with reactivation. *In vitro*, HHV-6 resembles CMV in its antiviral susceptibilities. It is resistant to acyclovir but susceptible to ganciclovir and foscarnet. No clinical trials have been undertaken.

Acute Disseminated Encephalomyelitis

Acute disseminated encephalomyelitis (ADE) may occur in the course of various infections, particularly the acute exanthematous diseases of childhood, and following vaccinations; thus, ADE is also known by the terms *post- or parainfectious encephalomyelitis* (PIE) and *postvaccinal encephalomyelitis*. The clinical symptoms and the pathologic changes are similar in all of these cases, regardless of the nature of the precipitating infection or vaccination.

Etiology and Pathogenesis

The list of diseases that may be accompanied or followed by signs and symptoms of an encephalomyelitis is probably not yet complete, but it includes measles, rubella, varicella, smallpox, mumps, influenza, parainfluenza, infectious mononucleosis, typhoid, mycoplasmal infections, and upper respiratory and other obscure febrile diseases, as well as vaccination against measles, mumps, rubella, influenza, and rabies. Reactions in the nervous system may also follow inoculations with typhoid vaccine and with sera, particularly that against tetanus. In these latter conditions, the clinical picture is more likely to be that of a mononeuritis or generalized

polyneuritis.

The pathogenesis of ADE is not known. Because virus is not usually isolated from the nervous system of patients, an allergic or autoimmune reaction appears to be most likely. Presumably, the virus triggers an immune-mediated reaction against CNS myelin, causing a disease similar to experimental allergic encephalomyelitis. This could possibly involve an extraneural interaction of a virus with the immune system without viral invasion of the nervous system.

Pathology

Little or no change occurs in the external appearance of the brain or spinal cord. On sectioning, many small yellowish-red lesions are present in the white matter of the cerebrum, cerebellum, brainstem, and spinal cord. The characteristic feature of these lesions is a loss of myelin, with relative sparing of the axis cylinders. Brain lesions are oval or round and usually surround a distended vein. Lesions are usually found in large numbers in almost all parts of the CNS, but in some cases they may be concentrated in the white matter of the cerebrum, while in others the cerebellum, brainstem, or spinal cord may be most severely affected. On microscopic examination, there is perivenular lymphocytic and mononuclear cell infiltration and demyelination. On myelin-stained specimens, there is destruction of myelin sheaths within the lesions, with a fairly sharp margin between the affected and normal areas. Axis cylinders are affected secondarily to a much lesser extent than the myelin sheaths. Phagocytic microglial cells may also be found within lesions and in perivascular spaces of adjacent vessels. Although lesions are concentrated in the white matter, a few patches may be found in the gray matter. Occasionally, nerve cells in these areas may be destroyed or may show various degenerative changes. ADE and PIE are monophasic diseases, as lesions have a similar age of onset. *Acute hemorrhagic leukoencephalitis* appears to be a fulminant form of ADE or PIE. Pathologic lesions are similar to those of ADE with the addition of microscopic hemorrhages and perivascular PMN cell infiltrates.

Epidemiology

Previously, smallpox vaccination (vaccinia virus) was one of the more frequent causes of PIE or postvaccinal encephalomyelitis. The exact frequency has not been accurately established because of the wide range reported, varying from more than 1 case per 100 to less than 1 case per 100,000 vaccinees. Because smallpox has apparently been eradicated as a natural disease, vaccination is no longer recommended. Thus, vaccinia virus is no longer a common cause of PIE. The smallpox virus (variola virus) also probably caused this syndrome in the past.

The incidence of encephalomyelitis following vaccination against rabies with the old nerve-tissue-prepared vaccines ranged as high as 1 in 600 persons, with a mortality rate of 10% to 25%. With the duck-embryo vaccine, this complication has decreased to approximately 1 in 33,000 recipients. This complication has rarely been reported with the new human diploid cell vaccine (several cases); there have also been a few cases of Guillain-Barré syndrome.

Damage to the nervous system with the acute exanthems occurs most commonly following measles, for which the incidence is approximately 1 in 1,000 persons. In countries using measles vaccination, however, measles is no longer a common cause of PIE. The incidence following measles vaccine is only about 1 in 1 million recipients. PIE followed rubella or mumps much less frequently than it did natural measles, but even this occurrence has decreased with vaccination. VZV infections are now probably the more common cause of PIE, although the exact incidence is not known. Nonspecific upper respiratory infections are probably the most common overall cause.

Symptoms and Signs

The symptoms and signs of ADE or PIE are related to the portion of the nervous system that is most severely damaged. Because any portion of the nervous system may be affected, it is not surprising that variable clinical syndromes may occur. In some cases, there are signs and symptoms of generalized involvement (ADE), but one or more portions of the neuraxis may suffer the brunt of the damage, resulting in various clear-cut clinical syndromes: meningeal, encephalitic, brainstem, cerebellar, spinal cord, or neuritic.

Symptoms of involvement of the meninges (headaches, neck stiffness) are common early in the course of all types. In some cases, no further symptoms are present. In others, these initial symptoms and signs may be followed by evidence of damage to the cerebrum. In this *encephalitic form*, there may be convulsions, stupor, coma, hemiplegia, aphasia, or other signs of focal cerebral involvement. Cranial nerve palsies, especially *optic neuritis*, or signs and symptoms of cerebellar dysfunction predominate in a few cases. *Acute cerebellar ataxia* constitutes about 50% of cases of PIE following varicella, whereas cerebral and spinal involvement are more common with measles and vaccinia.

Overall, spinal cord involvement is more common than involvement of either the brainstem or cerebellum. This may be disseminated in the cord or, more commonly, may take the form of an *acute transverse myelitis* or *acute transverse myelopathy* (ATM), a syndrome of multiple causes. It may be acute, developing over hours to several days, or subacute, developing over 1 to 2 weeks. The most common picture is a transverse myelitis interrupting both motor and sensory tracts at one level, usually thoracic. It usually begins with localized back or radicular pain followed by abrupt onset of bilateral paresthesia in the legs, an ascending sensory level, and a paraparesis that often progresses to paraplegia. Urinary bladder and bowel involvement occurs early and is prominent. In general, patients with rapid progression and flaccidity below the level of the lesion have the worst prognosis. The syndrome may also take the form of an ascending myelitis, a diffuse or patchy myelitis, or a partial myelitis (Brown-Séquard syndrome, anterior spinal artery distribution lesion, posterior column myelopathy). Only about 25% to 33% of cases of ATM are caused by viral infections or vaccinations via a demyelinating process. Less frequently, a complete transverse myelitis may result from direct virus invasion of the cord (e.g., poliovirus or herpesviruses). Other less frequent causes of ATM include systemic lupus erythematosus, other vasculitides, other causes of spinal cord infarction, multiple sclerosis, and trauma. Idiopathic ATM is most frequent. Obviously, it is important to exclude cord compression by epidural abscess or tumor, intrinsic cord bacterial or fungal infections, tumors, and treatable vascular diseases.

Other parainfectious syndromes may also be seen. Acute toxic encephalopathy and Reye syndrome are seen more frequently after varicella, influenza, and rubella. Peripheral nerve involvement with an acute ascending paralysis of the Guillain-Barré type is more frequent with rabies vaccine, especially with the older preparations, and after influenza and upper respiratory infections. Brachial neuritis is the usual neurologic complication of antitetanus vaccine.

Laboratory Studies

The CSF pressure may be slightly elevated. There is a mild to moderate increase in white cells (15 to 250 cells/mm³), with lymphocytes as the predominating cell type. The protein content is normal or slightly elevated (35 to 150 mg/dL); the sugar content is within normal limits. The CSF myelin basic protein level is usually increased. The EEG is abnormal in most patients, usually with slow frequency of 4 to 6 Hz and high voltage. The abnormalities are usually generalized and symmetric, but focal or unilateral changes may be found. The abnormalities persist for several weeks after apparent clinical recovery. Persisting abnormalities correlate well with permanent neurologic damage or convulsive disorders. After several days, CT may show diffuse or scattered low-density lesions in the white matter, some of which may enhance with contrast. MRI usually reveals an increased signal intensity on T2-weighted images ([Fig. 23.5](#)).

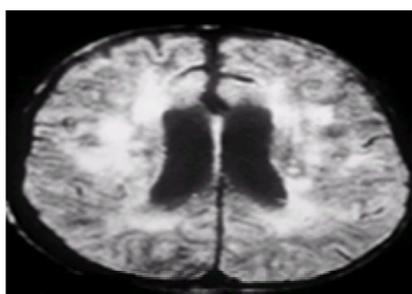

FIG. 23.5. Postinfectious encephalitis. Proton-density MR image shows a lesion that began 2 weeks after a nonspecific upper respiratory tract infection. There is prominent diffuse cerebral white matter disease. (From Jubelt B, Ropka S. Infectious diseases of the nervous system. In: Rosenberg RN, ed., *Atlas of clinical neurology*. Philadelphia: Current Medicine, 1998:12.1–12.71; with permission.)

Diagnosis

Because there is no specific diagnostic test, the diagnosis of PIE or postvaccinal encephalomyelitis should be considered when neurologic signs develop 4 to 21 days following onset of acute exanthems or an upper respiratory tract infection, or after vaccination. The differential diagnosis includes practically all the acute infectious diseases of the nervous system, particularly acute or subacute encephalitis, and acute diffuse multiple sclerosis.

Prognosis and Course

The mortality rate is high (10% to 30%) in patients with severe involvement of the cerebrum in measles or rubella, or after rabies vaccination with the old brain-derived vaccine. It is low in patients with acute cerebellar ataxia or involvement only of the peripheral nerves. Death may occur as a result of cerebral damage in the acute stage or following intercurrent infections, bed sores, or urinary sepsis in late stages. In patients who survive, the neurologic signs usually improve considerably, with about 90% having complete recovery. The exception is measles, in which sequelae may occur in 20% to 50% of patients. Sequelae include seizures, mental syndromes, and hemiparesis. Delayed postencephalitic sequelae, such as parkinsonism, do not occur; as a rule, there are no new symptoms after recovery from an acute attack.

Treatment

Several reports suggest that the administration of adrenocorticotrophic hormone or intravenous corticosteroids reduces the severity of the neurologic defects.

CHRONIC VIRAL INFECTIONS

Chronic or slow viral infections that result in chronic neurologic disease are caused by both conventional viruses and the unconventional transmissible spongiform encephalopathy agents. However, the transmissible spongiform encephalopathy agents, or prions, as presently understood, are not true viruses (see [Chapter 33](#)). Conventional agents cause chronic inflammatory or demyelinating disease; in humans, these include subacute sclerosing panencephalitis (SSPE), progressive rubella panencephalitis (PRP), progressive multifocal leukoencephalopathy (PML), human T-cell lymphotropic virus (HTLV)-associated myelopathy (HAM)/tropical spastic paraparesis (TSP), and AIDS. In SSPE, a chronic inflammatory disease is caused by a defect in the production of measles virus, which results in a cell-associated infection. With PRP, both inflammation and demyelination may be seen. The pathogenic mechanisms have not yet been defined, but the virus does not appear to be defective. PML is a noninflammatory demyelinating disease that occurs in immunocompromised hosts; it is caused by an opportunistic papovavirus infection. HAM/TSP is an inflammatory demyelinating disease caused by HTLV, a retrovirus. AIDS is reviewed in [Chapter 24](#). Other conventional viruses (enteroviruses, HSV, VZV, CMV, measles virus, adenovirus) can cause chronic opportunistic infections in immunocompromised patients.

Subacute Sclerosing Panencephalitis

SSPE (Dawson disease or subacute inclusion body encephalitis) is a disease caused by a defective measles virus. It is characterized by progressive dementia, incoordination, ataxia, myoclonic jerks, and other focal neurologic signs. First described by Dawson in 1933 and 1934 as "subacute inclusion encephalitis," it was thought to be of viral origin because of the presence of type A intranuclear inclusions. Numerous cases have since been reported, but recovery of a viral agent was not possible until the advent of specialized techniques of viral isolation by cocultivation of brain cells with extraneural cells capable of replicating fully infectious virus. The cases reported by Pette and Doring in 1939 as "nodular panencephalitis" and by Van Bogaert in 1945 as "subacute sclerosing leukoencephalitis" appear to involve the same disease. The name of this disease reflects a combination of the three terms.

Pathology

In severe long-standing cases, the brain may feel unduly hard. A perivascular infiltration occurs in the cortex and white matter with plasma and other mononuclear cells. Patchy areas of demyelination and gliosis occur in the white matter and deeper layers of the cortex. The neurons of the cortex, basal ganglia, pons, and inferior olives show degenerative changes. Intranuclear and intracytoplasmic eosinophilic inclusion bodies are found in neurons and glial cells. When examined with the electron microscope, these inclusions are seen to be composed of hollow tubules similar to the nucleocapsids of paramyxoviruses. Staining of inclusions by the fluorescent antibody method shows that they are positive for measles virus.

Incidence

Children younger than 12 years are predominantly affected, although a few cases in adults in their 20s have been reported. Boys are more often affected than girls, and more cases have occurred in rural than in urban settings. The incidence of SSPE has decreased markedly in the United States since the introduction of the live attenuated measles vaccine. After natural measles infection, the incidence of SSPE is 5 to 10 cases per 1 million clinical measles infections. After vaccine, the rate is less than 1 case per 1 million vaccine recipients.

Symptoms

SSPE has a gradual onset without fever. Forgetfulness, inability to keep up with schoolwork, and restlessness are common early symptoms. These are followed in the course of weeks or months by incoordination, ataxia, myoclonic jerks of the trunk and limbs (often noise-induced), apraxia, and loss of speech; seizures and dystonic posturing may occur. Vision and hearing are preserved until the terminal stage, in which there is a rigid quadriplegia simulating complete decortication.

Laboratory Data and Diagnosis

Elevated levels of measles antibody can be found in serum and CSF. The CSF is under normal pressure, and the cell count is normal or, rarely, only slightly increased. The protein content is normal, but a striking increase in the CSF immunoglobulin content is found, even in an otherwise normal fluid. Oligoclonal IgG bands, representing measles virus-specific antibodies, can be demonstrated by agarose electrophoresis of CSF. The EEG often shows a widespread abnormality of the cortical activity with a "burst suppression" pattern of high-amplitude slow-wave (or spike and slow-wave) complexes occurring at a rate of every 4 to 20 seconds synchronous with or independent of the myoclonic jerks. CT may show cortical atrophy and focal or multifocal low-density lesions of the white matter.

Pathogenesis

A defect in measles virus production seems to occur because the viral M (membrane) protein cannot be found in the brain tissue of affected patients. The M protein is necessary for alignment of nucleocapsids under viral proteins in the cell membrane so that budding of virus can take place. Thus, in SSPE there is no budding and no release of extracellular virus. There is accumulation of measles virus nucleocapsids within cells (cell-associated infection), and virus spread occurs by cell fusion. Brain cells may be incapable of synthesizing the M protein, or selective antibody pressure might cause a restricted cell-associated infection, because more than 50% of patients with SSPE have had an acute measles infection before reaching 2 years of age, when maternal antibody may still have been present.

Course, Prognosis, and Treatment

The course of the disease is prolonged, usually lasting several years. Both rapidly progressive disease, leading to death in several months, and protracted disease, lasting more than 10 years, have occurred. Spontaneous long-term improvement or stabilization occurs in about 10% of patients. There is no definite specific therapy. Intrathecal interferon alfa with or without isoprinosine (inosine pranobex, Imunovir) may induce remissions. No controlled studies have been performed.

Progressive Rubella Panencephalitis

Rubella virus, like measles virus, has been recognized to cause slowly progressive rubella panencephalitis. This is a rare disease of children and young adults. Fewer than a dozen cases have been reported. Most cases have occurred in patients with the congenital rubella syndrome, but several cases have appeared following postnatally acquired rubella. None has been ascribed to rubella vaccine. There does not appear to be a defect in rubella virus production, as occurs in SSPE. Unlike

measles virus, rubella virus does not have an M protein. Because of the recognition that immune complexes are in the serum and CSF, it is thought that immune complex deposition in vascular endothelium results in vasculitis.

The pathologic condition is characterized by inflammation and demyelination. The inflammation consists of lymphocytic and plasma cell infiltration of the meninges and perivascular spaces of the gray and white matter. Extensive demyelination with atrophy and gliosis of the white matter is usually seen, together with vasculitis involving arterioles with fibrinoid degeneration and mineral deposition. Arterioles may be thrombosed, and there are adjacent microinfarcts. IgG deposits have been demonstrated in vessels.

PRP usually occurs in the second decade of life, beginning with dementia similar to that of SSPE. Cerebellar ataxia, however, is more prominent. Gait ataxia is initially seen, but the arms subsequently become involved. Later, pyramidal tract involvement is seen. Optic atrophy and retinopathy similar to those seen in congenital rubella occur. Seizures and myoclonus are not prominent. Symptoms and signs suggestive of infection (headache, fever, nuchal rigidity) are not seen.

Routine blood tests are normal. The EEG reveals diffuse slowing; periodicity is rare. CT may demonstrate ventricular enlargement, which is most prominent in the fourth ventricle and cisterna magna because of cerebellar atrophy. The CSF is under normal pressure. There is usually a lymphocytic pleocytosis with up to 40 cells/mm³, but the fluid is occasionally acellular. The protein is increased in the range of 60 to 150 mg/dL, with the IgG fraction being up to 50% of this. Most of the IgG is composed of oligoclonal bands directed against rubella virus. Conventional serologic techniques demonstrate elevated serum and CSF antibody titers against rubella virus. Recovery of the virus is difficult and requires cocultivation.

The diagnosis can easily be made in a patient with the congenital rubella syndrome. In postnatally acquired cases, SSPE is the other major diagnostic consideration. Other dementing illnesses of childhood should be considered; however, the combined data of the clinical picture (especially when ataxia ensues), the CSF findings, and serology should be diagnostic. The course is protracted over 8 to 10 years. There is no specific treatment.

Retrovirus Infections

HIV Infection

See [Chapter 24](#).

HTLV-associated Myelopathy/Tropical Spastic Paraparesis

Etiology

HTLV is a retrovirus that causes adult T-cell leukemia and a chronic progressive myelopathy, hereditary and acquired spastic paraplegia (see [Chapter 117](#)). This chronic HTLV-associated myelopathy (HAM) has been referred to as tropical spastic paraparesis (TSP) in tropical areas, hence the abbreviation HAM/TSP. Of the two serotypes of HTLV, most cases of HAM/TSP are caused by HTLV-I.

Pathology and Pathogenesis

Patients have a mild chronic meningoencephalomyelitis with mononuclear infiltrates of the meninges and perivascular cuffing primarily in the spinal cord. In addition, there are proliferation of smaller parenchymal vessels, thickening of the meninges, and a reactive astrocytic gliosis. A second prominent feature is demyelination in the pyramidal tracts and posterior columns.

Like HIV, HTLV apparently enters the CNS via infected peripheral blood mononuclear cells, thereby causing secondary infection of glial cells. Presumably, demyelination is caused by cytotoxic T cells rather than by direct infection with HTLV.

Epidemiology

TSP occurs in tropical islands (including the Caribbean), as well as in tropical areas of the United States, Central and South America, India, and Africa. The prevalence is quite variable, ranging from 12 to 128 cases per 100,000 population. HAM is found on the southwestern and northern islands of Japan; the prevalence is not known. The temporal behavior of HAM/TSP reflects an endemic myelopathy. Most cases occur after age 30 years, but childhood cases have been reported. There is a female preponderance.

More cases of HAM/TSP are being recognized throughout the United States, in both immigrants and native residents. As in HIV infection, exposure is related to intravenous drug use, sexual transmission, and blood transfusions.

Symptoms and Signs

Onset is usually gradual, with weakness of one leg followed in several months by weakness of the other leg. Other complaints include numbness and dysesthesia, bladder dysfunction, and impotence. Infrequently, more abrupt onset may occur. Examination reveals spastic paraparesis with overactive tendon reflexes (legs more than arms) and Babinski signs. Posterior column dysfunction is common, and hypesthesia is often noted diffusely below the midthoracic level. Less frequently, a distinct sensory level or peripheral neuropathy (25%) is found. Cerebral involvement caused by white matter disease and made evident by encephalopathy and seizures has been described in several patients. Neurogenic muscular atrophy and polymyositis occur rarely.

Laboratory Studies

CSF examination may be entirely normal, but a mild lymphocytic pleocytosis may be seen. About 50% of patients have an elevated CSF protein content in the 50- to 90-mg/dL range. Increased CSF IgG levels and oligoclonal bands are found in most patients. Antibodies to HTLV are increased in both serum and CSF. The ratio of helper to suppressor T cells is increased. MRI may show white matter lesions in the brain, even in asymptomatic patients.

Diagnosis

Diagnosis depends on the appropriate clinical and CSF manifestations and a positive antibody response in the serum and CSF. The differential diagnosis includes other causes of spastic paraparesis, including multiple sclerosis (see [Chapter 117](#) and [Chapter 133](#)).

Course, Prognosis, and Treatment

Most patients progress slowly over months to a few years and may stabilize. Responses to corticosteroids and danazol (Danocrine) have been reported in uncontrolled studies. In a recent double-blind, controlled trial, two-thirds of patients reported benefit from interferon alfa.

Progressive Multifocal Leukoencephalopathy

PML is a rare subacute demyelinating disease caused by an opportunistic papovavirus. The disease occurs in patients with defective cell-mediated immunity. Cases have primarily occurred in patients with reticuloendothelial diseases, such as Hodgkin disease, other lymphomas, and leukemia before the AIDS epidemic. Cases have also occurred in patients with carcinoma or sarcoidosis and in those immunosuppressed therapeutically. In most of these disorders, PML is a rare complication; it occurs in 2 to 5% of AIDS patients. A few cases have occurred in the apparent absence of an underlying disease.

Pathology

The condition is characterized by the presence of multiple, partly confluent areas of demyelination in various parts of the nervous system, accompanied at times by a

mild degree of perivascular infiltration. These multifocal areas of demyelination are most prominent in the subcortical white matter, whereas involvement of cerebellar, brainstem, or spinal cord white matter is less common. As the disease progresses, the demyelinated areas coalesce to form large lesions. Hyperplasia of astrocytes into bizarre giant forms that may resemble neoplastic cells is found. There is loss of oligodendroglia with relative sparing of axons in the lesions. Eosinophilic intranuclear inclusions are seen in oligodendroglial cells at the periphery of the lesions. Electron microscopic studies have shown that these inclusions are composed of papovavirus particles (Fig. 23.6). It is presumed that the demyelination is due to destruction of oligodendroglia by the virus. Most cases have been caused by the JC strain and possibly several by the SV-40 strain. Isolation of these agents requires special techniques of cocultivating brain cultures from patients with permissive cell lines; human fetal brain tissue could also be used to induce virus replication.

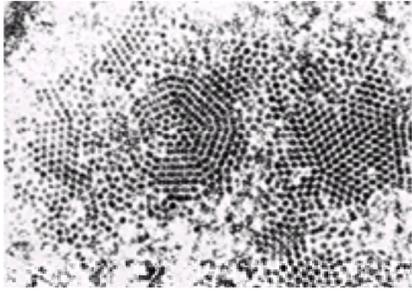

FIG. 23.6. Progressive multifocal leukoencephalopathy. Papovavirus-like particles are present in a glial nucleus (x65,000). (Courtesy of Dr. G.M. Zu Rhein.)

Symptoms and Signs

The clinical manifestations are diverse and are related to the location and number of lesions. Onset is subacute to chronic with focal or multifocal signs (hemiplegia, sensory abnormalities, field cuts, and other focal signs of lesions in the cerebral hemispheres). Cranial nerve palsies, ataxia, and spinal cord involvement are less common. As the number of lesions increases, dementia ensues.

Laboratory Data and Diagnosis

A definite diagnosis of PML can be made only by pathologic investigation (brain biopsy). Eventually, PCR amplification of JC virus RNA in the CSF should obviate brain biopsy. Virus isolation techniques are difficult and time-consuming. More rapid identification can be made by immunofluorescence or by immune electron microscopy. The CSF is usually normal. The EEG often demonstrates nonspecific diffuse or focal slowing. CT reveals nonenhancing multiple lucencies in the white matter. MRI may demonstrate additional white matter abnormalities (Fig. 23.7). Serology is not helpful because most people have been exposed to the JC strain in the first two decades of their lives. A presumptive diagnosis can be made on the basis of the clinical presentation and the appropriate CT findings in an immune-compromised patient.

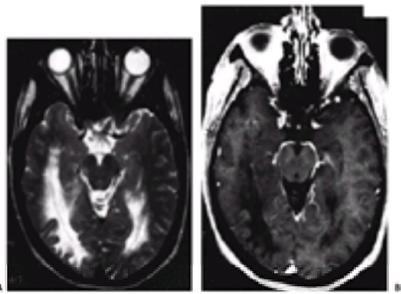

FIG. 23-7. Progressive multifocal leukoencephalopathy. **A:** T2-weighted spin-echo axial MR image shows increased signal intensity of the temporooccipital white matter, which is greater on the right than the left. Relative cortical sparing is seen. **B:** T1-weighted gradient-echo axial MR image after gadolinium administration shows decreased signal intensity in the same areas with no evidence of abnormal enhancement. Note the normal enhancement of both internal carotid arteries and posterior cerebral arteries on the gradient-echo enhanced images. (Courtesy of Dr. S. Chan, Columbia University College of Physicians and Surgeons, New York, N.Y.)

Pathogenesis

Apparently, the virus is latent in the kidney and in B lymphocytes and enters the CNS in activated B lymphocytes. Once virus enters the brain, glial cells (astrocytes and oligodendroglia) support virus replication because viral transcription factors are selectively expressed in these cells.

Course, Prognosis, and Treatment

The course usually lasts months, and 80% of patients die within 9 months. Rarely, the course may last several years, with the longest verified course recorded at 6 years. In most patients with AIDS, the inflammatory response has been prominent and the course longer than that noted with other underlying disease. If possible, treatment should include an attempt to improve immune function. There is no definite treatment. Spontaneous improvement has been reported.

Encephalitis Lethargica

Encephalitis lethargica (sleeping sickness, von Economo disease) is a disease of unknown cause that occurred in epidemic form from 1917 to 1928. Clinically, the disease was characterized by signs and symptoms of diffuse involvement of the brain and the development of various sequelae in a large percentage of recovered patients. Although the disease spread rapidly over the entire world, the epidemic form is apparently extinct. It may now occur as very rare isolated cases. Encephalitis lethargica affected patients of all ages and both sexes equally, including people of all races and occupations.

The etiology of encephalitis lethargica is unknown. It is presumed that the disease was caused by a virus, but proof is lacking. Because of the concurrence of encephalitis lethargica and the pandemic of influenza beginning in 1918, there has been speculation about a common etiology; this has not been resolved but is probably unlikely.

The pathologic lesions in the subacute stages were similar to those of other encephalitides, with inflammation in the meninges, around blood vessels, and in the parenchyma (both gray and white matter) of the brain and spinal cord. Acute degenerative changes of neurons also occurred.

The symptoms and signs were usually of acute or subacute onset. Fever was usually present at the outset and was usually mild. In fatal cases, a rise to 107°F (41.7°C) or higher often occurred in the terminal stages. Headache and lethargy were common early symptoms. Disorders of eye movements were present in about 75% of patients. An acute organic psychosis was not uncommon. The most frequent motor symptoms were all categories of basal ganglia diseases.

Pertinent laboratory studies showed a lymphocytic pleocytosis in the CSF and an abnormal CSF protein content in about 50% of patients.

The diagnosis of encephalitis lethargica may be justified in any patient with signs and symptoms of encephalitis with special features of disturbed sleep rhythm and diplopia in the acute stage, and the development of signs of injury of the basal ganglia at that time or in subsequent years. The duration of the acute stage was about 4 weeks and merged gradually into the so-called postencephalitic phase of the disease. The mortality rate was about 25% and was highest among infants and elderly persons.

The frequency of sequelae is unknown. In some instances, symptoms were merely a continuation of those present in the acute stage. In others, the symptoms developed after an interval of several months or many years, during which the patient was apparently well. The parkinsonian syndrome that develops after encephalitis lethargica can often be distinguished from idiopathic parkinsonism because of an early age of onset and unusual features, such as grimaces, torticollis, torsion spasms, myoclonus, oculogyric crises, facial and respiratory tics, and bizarre postures and gaits. Behavior disorders and emotional instability without evidence of intellectual impairment were common sequelae in children.

Enterovirus (Picornavirus) Infections

HISTORY

Acquired immunodeficiency syndrome (AIDS) was first recognized clinically in 1981. In 1982, the Centers for Disease Control (CDC) proposed epidemiologic surveillance criteria for the diagnosis of AIDS as the occurrence of unusual opportunistic infections (OIs) or malignancies indicative of a defect in cell-mediated immunity without a known cause.

In 1983, human immunodeficiency virus type 1 (HIV-1), the retrovirus that causes AIDS, was isolated from human peripheral blood lymphocytes. An explosive pace of research followed. The virus was sequenced and its structure elucidated by x-ray crystallography. There were rapid advances in understanding of the viral life cycle, mechanisms of human infection and pathogenesis, and development of successful drug therapies. The cellular immune defect of AIDS was attributed to HIV infection of CD4 (T4 helper) lymphocytes. Soon after infection, HIV replicates vigorously in peripheral blood lymphocytes and lymphoid tissues throughout the body, including gut-associated lymphoid, brain microglial, and macrophage cells. Disseminated viral infection causes systemic and neurologic disorders, such as the wasting syndrome and dementia that are now recognized as AIDS-defining illnesses, even in the absence of OIs or neoplasia.

Serologic studies showed that there can be a latency of several years between HIV infection and AIDS, the latter indicative of advanced immunosuppression. Direct viral nucleic acid detection (viral load) and viral replication assays showed that there is no virologic latency after initial infection. Despite ongoing viral replication, most infected people are asymptomatic or experience transient self-limited illnesses. Some have chronic lymphadenopathy or the AIDS-related complex of adenopathy, weight loss, fever, and diarrhea.

CLASSIFICATION OF HIV DISEASE

The CDC proposed staging criteria for HIV infection in 1986, which were modified in 1987 to include the neurologic syndromes of AIDS dementia and myelopathy among 23 AIDS-defining illnesses ([Table 24.1](#)). Future revisions were anticipated, based on improved understanding of HIV biology. The 1993 revisions added three laboratory categories stratified by CD4 cell counts and three clinical categories ([Table 24.2](#)). AIDS-defining illnesses were expanded to include positive HIV serology and pulmonary tuberculosis, recurrent bacterial pneumonia, invasive cervical carcinoma, or a CD4 lymphocyte count less than 200/mm³. The revisions defined the end stage of HIV infection and clarified the relationship of specific clinical syndromes that are not diagnostic of AIDS, especially neurologic disease, to advanced immunosuppression.

Group I	Acute infection (transient symptoms with seroconversion)
Group II	Asymptomatic infection (seropositive only)
Group III	Persistent generalized lymphadenopathy
Group IV	Other disease
Subgroup A	Chronic constitutional disease
Subgroup B	Neurologic disease
Subgroup C	Specified secondary infections
Category C-1	Diseases listed in the CDC definition for AIDS
Category C-2	Other specified secondary infections
Subgroup D	Specified secondary cancers (includes cancers fulfilling CDC definition of AIDS)
Subgroup E	Other conditions

From Centers for Disease Control. *MMWR* 1986;35:334-339.

TABLE 24.1. RECLASSIFICATION OF HIV INFECTION

Laboratory categories	
1	CD4 lymphocyte count >500 cells/mm ³
2	CD4 lymphocyte count from 200-499 cells/mm ³
3	CD4 lymphocyte count <200 cells/mm ³
Clinical categories	
A	Asymptomatic infection, persistent generalized lymphadenopathy, and acute primary HIV infection
B	Symptomatic conditions not included in the CDC's 1987 surveillance case definition of AIDS that are judged by a physician to be HIV-related or whose medical management is complicated by HIV infection (e.g., hepatitis, bacterial endocarditis, pulmonary tuberculosis, cervical dysplasia or carcinoma, vulvovaginal candidiasis)
C	Any of the 23 conditions listed in the CDC's 1987 case definition for AIDS

Adapted from US Congress. CDC's case definition of AIDS: implications of the proposed revisions background paper. Washington, DC: US Government Printing Office, 1992. OFA-EP-92-09.

TABLE 24.2. CDC CLASSIFICATION OF HIV INFECTION

The classification system guides medical management of HIV-infected persons. The Walter-Reed classification system has not gained wide acceptance.

HIV replication (*viral load*) is the determining factor in progression to clinical endpoints such as AIDS or death. Viral load assays have supplanted staging criteria for decisions about antiretroviral therapy. Staging is still useful for prognosis and decisions about OI prophylaxis.

EPIDEMIOLOGY

General Picture

HIV infection is a worldwide pandemic affecting virtually all population groups, with especially rapid spread in developing countries, where 90% of new cases occur. Transmission occurs through homosexual or heterosexual contact, exposure to contaminated blood or blood products, or perinatally. Worldwide, heterosexual activity is the most common mode of transmission. In the United States, homosexual activity is slightly more frequent than injection-drug use (IDU) as the most common exposure but seroconversion is more common in IDU. In western Europe, IDU accounts for 40% of cases and homosexual activity for 35%.

Retrospective analysis of banked blood showed that HIV was present in the United States in the 1970s. By September 1997, the cumulative total of AIDS cases reported to the CDC was 626,334; cases in New York, Florida, New Jersey, California, and Puerto Rico accounted for 64% of the total. Eighty percent of cases were in the Northeast (44%) and the South (36%); 85% of cases had a defined transmission risk. Of 91,837 cumulative cases reported by 1997 without a known transmission category, 41,391 (31,190 men, 10,201 women) were assigned to one of the recognized categories. Homosexual activity was the most common unrecognized risk for 57% of men and heterosexual activity for 67% of women. Recipients of blood products or clotting factor for hemophilia or other coagulation or blood disorders accounted for less than 1% of adult AIDS cases in 1997. Routine testing of blood products has largely eliminated this source of infection in the United States.

Occupational exposure with documented transmission and seroconversion has occurred in 52 health care workers: 45 had percutaneous exposure, five had mucocutaneous exposure, and two had both mucocutaneous and percutaneous exposure. Most exposures were to blood or bloody fluid. Possible occupational transmission has occurred in 114 additional health care workers who were exposed to HIV-contaminated blood, body fluids, or laboratory solutions, but HIV seroconversion after a specific occupational exposure was not documented. Prospective studies of known exposures estimate the average risk for HIV transmission after a percutaneous exposure to HIV-infected blood as approximately 0.3% and after mucous membrane exposure 0.09%. There were no documented cases of seroconversion after isolated skin exposure.

The first 100,000 AIDS cases were reported in 8 years; more than 500,000 cases were reported in the second 8-year period. Changes in the case definition were responsible for a transient increase in AIDS cases. The AIDS case definition may become less relevant as more states require integrated HIV/AIDS case reporting. Dual reporting allows accurate assessment of the scope and demographics of the epidemic, appropriate funding initiatives, and identification of persons for counseling about treatment. There are also increased efforts to identify contacts. The fastest growing populations with AIDS in the United States are women, African-American and Hispanic minorities, and injection-drug users (Table 24.3). A rise in seroconversion among some young homosexual male populations implies a need for continued vigilance in targeted education. In 1994, AIDS became the leading cause of death among men and African-American women. The disproportionate representation of African-American and Hispanic men is related to drug use. Minority women are also directly or indirectly affected by drug use, but unprotected heterosexual activity has become the predominant transmission risk.

	First 100,000 Cases (%)	Second 100,000 Cases (%)
Homosexual/bisexual men	61	55
Intravenous drug users, men and women	20	24
Heterosexual transmission	5	7
Women	9	12
Children	1.6	1.7
African-American adults	27	31
Hispanic adults	15	17

Modified from Centers for Disease Control. *MMWR* 1991; 4:164.

TABLE 24.3. EPIDEMIOLOGY OF AIDS: THE FIRST AND SECOND 100,000 CASES

HIV infection has been reported in virtually every country. In developing countries, rapid spread is related to inadequate public health and health care infrastructures. The World Health Organization estimated that 30,000,000 people worldwide are currently infected. There were 2.3 million deaths from AIDS by 1997, 50% higher than in 1996. Globally, there are an estimated 16,000 new cases of HIV infection daily. Although unprotected heterosexual activity is the predominant transmission risk, there are substantial risks in health care settings due to contaminated blood or needles.

AIDS in Children

By September 1997, 7,310 children younger than 13 with HIV infection were reported to the CDC, slightly more than 1% of all AIDS cases, most infected perinatally. Perinatal infection disproportionately affects African-Americans and Hispanics, a measure of their disproportionate number among seropositive women. Since 1992, perinatal transmission in the United States has declined 43% due to successful implementation of CDC guidelines for maternal zidovudine (Retrovir) treatment. Worldwide, perinatal transmission unfortunately continues because treatment is not available. Children account for more than 1,000,000 of worldwide AIDS cases, with 350,000 annual infections. Millions of uninfected children will be orphaned by the loss of both parents to AIDS.

ETIOLOGY

Virologic, serologic, and epidemiologic data support the conclusion that AIDS is caused by HIV infection. HIV is an enveloped ribonucleic acid (RNA) virus. It contains an RNA-dependent, DNA polymerase (reverse transcriptase) that produces a provirus capable of integrating into host-cell DNA. In the target cell, the virus exists in both free and integrated states. It is a lentivirus. The best-known of this family is visna virus, which, like HIV, demonstrates cellular tropism, establishes persistent infection, and after long clinical latency establishes a slowly progressive demyelinating disease in ovines.

Human HIV infection is considered a cross-species (zoonotic) infection arising from monkeys infected with simian immunodeficiency virus (SIV) through multiple independent transmissions. Of the two recognized viral species, HIV-1 is found worldwide and is more prevalent, whereas HIV-2 is found in western Africa and in Europe among African immigrants and their sexual partners. Sporadic cases of HIV-2 infection occur in the United States. HIV-2 less frequently causes immunodeficiency and AIDS than HIV-1. There are phylogenetic groups of HIV-1 (M, N, and O), and each comprises several viral strains. Group M (the main group) is responsible for the global epidemic. Group O (the outlier) is found in Cameroon, Gabon, and Equatorial Guinea. Group N (non-M/non-O) was isolated from two individuals in Cameroon.

SIV was first isolated from macaque monkeys in captivity and later found in African green monkeys. The sooty mangabey is the primate host suspected of transmitting HIV-2. This subspecies is infected with a strain of SIV that is genomically and phylogenetically related to HIV-2. Its natural habitat is the epicenter of the HIV-2 epidemic, and large numbers of wild animals are infected. The chimpanzee seems to be the primate host for HIV-1. The recognition of HIV infection as a zoonosis raises concern for animal-to-human transmission of other potentially pathogenic retroviruses.

Although scientific data overwhelmingly support the view that HIV is the cause of AIDS, other theories have been proposed, including toxic drug exposure or an as yet unidentified agent. In 1992, 35 cases of HIV-negative CD4 cell lymphopenia or AIDS were reported in the United States and six other countries. Some patients had risk factors associated with HIV; others had no reported risk factors. Alternative theories of infection lack substantial scientific support.

PATHOGENESIS

Infection of CD4 lymphocytes by HIV, mediated by viral attachment to the cell-surface CD4 receptor, leads to cell death. In humans, the CD4 receptor is expressed on several cell types, including neurons and glia in the brain, yet there is no evidence of viral replication in cells other than lymphocytes, macrophages, monocytes, and their derivatives. A coreceptor necessary for viral entry into cells was identified in 1996 as a chemokine receptor. In acute and early HIV infection, a macrophage-tropic viral strain predominates and uses the chemokine receptor CCR5 (R5 virus). In chronic infection, T-cell tropic strains predominate and use the receptor CXCR4 (X4 virus). Other chemokine receptors are sometimes used. Genetic variation in the chemokine receptor may affect susceptibility to HIV infection. Relative resistance to infection is observed in persons who are homozygous for a 32-base-pair deletion in CCR5.

Primary HIV infection may be asymptomatic or, as in 50% to 70% of patients, result in an acute, self-limited mononucleosis-like illness with fever, headaches, myalgia, malaise, lethargy, sore throat, lymphadenopathy, and maculopapular rash. Painful ulceration of the buccal mucosa may impede swallowing (odynophagia).

Acute infection is characterized by viremia, a high viral replication rate, ease of viral isolation from peripheral blood lymphocytes, and a high serum level of a viral core

antigen, p24. Initial viral load in acute infection may be as high as 10^6 RNA molecules per milliliter. Cytotoxic lymphocytes and soluble factors from CD8 lymphocytes are effective in reducing viral load to a set point that differs for each individual. Despite the effective early immune response, there is almost simultaneous immune dysfunction. Neutralizing antibodies of the immunoglobulin (Ig) M and, later, IgG type appear in 2 to 6 weeks, resulting in clearance of viremia and a decrease in serum p24 levels. Rarely, antibodies do not appear for several months and exceptionally not at all.

Adverse immunologic effects occur early and are more severe in symptomatic persons. An early absolute lymphopenia affects both CD4 helper and CD8 suppressor cells, with lymphocyte hyporesponsiveness to mitogens and antigens, and with thrombocytopenia. Lymphocytosis usually follows, especially of CD8 lymphocytes, with inversion of the CD4/CD8 ratio. Atypical lymphocytes are sometimes seen. Early changes in the CD4/CD8 ratio are usually transient, with reversion to more normal values but with persistent functional abnormalities. Cutaneous anergy is a direct result of the viral effects on CD4 cells.

After acute infection and seroconversion, clinical latency may last several years before the onset of symptoms of secondary infection, malignancy, or neurologic disease appears. There is no biologic latency, however; HIV infection is a chronic, persistent infection of variable viral replication rate.

The viral load set point after acute infection correlates with the rate of progression to symptomatic infection or AIDS. Several proprietary assays provide quantitative measurement of plasma HIV RNA. The branched (b)DNA assay detects as few as 20 to 50 copies/mL. Recognition of acute infection is important because early antiretroviral treatment may prevent extensive seeding of lymphoid tissues or may eliminate infection. Without treatment, viral replication is robust. It is estimated that 10^9 virions enter plasma daily in untreated people. Productively infected peripheral blood lymphocytes turn over rapidly with a half-life of 1.6 days. Most of the total viral load is in tissues, not plasma. In lymphoid tissue, virus is contained in two compartments: CD4+ lymphocytes or macrophages, and follicular dendritic cells within germinal centers, where virus is passively adherent. The total lymphoid viral burden is three times that of plasma, the majority in follicular dendritic cells. The total-body viral load is 10^{11} HIV-RNA copies. Approximately 10% of latently infected cells contain replication-competent provirus. Cellular destruction of lymphoid tissue is mediated by direct HIV cytopathic effects, autoimmunity, and other mechanisms. Eventually, the lymphoid system is overwhelmed by the viral burden, which increases with advancing disease, culminating in AIDS.

Other factors that may augment HIV replication and the onset of symptoms are biologic variability of HIV and the appearance of increasingly virulent strains; host immunogenetics; interaction with concomitant infection by cytomegalovirus (CMV), herpes simplex virus (HSV), hepatitis B (HBV) and C viruses, human herpesvirus 6, or human T-cell lymphotropic virus type 1, which upregulates expression of HIV; and upregulation of infection and cell-killing ability by cytokines. Cytokines are released by immune cells in response to infection and may upregulate or downregulate viral replication.

Other immunologic abnormalities in AIDS are caused by effects of HIV on immune cells other than the CD4 lymphocyte, such as B cells or macrophage. These include hypergammaglobulinemia; impaired antibody responses to new antigens, including encapsulated bacteria; and increased levels of immune complexes. Antibodies to platelets may cause thrombocytopenia. Loss of cellular immune function and impairment of B-cell and macrophage function increase susceptibility to some bacterial infections, opportunistic organisms, and rare neoplasms.

Highly active antiretroviral treatment (HAART) and specific prophylaxis have reduced the incidence of AIDS-related OIs and neoplasms in the United States. In untreated HIV infection, *Pneumocystis carinii* is the most common opportunistic pathogen. Other pathogens causing OIs are often multiple: fungal (candidiasis, cryptococcosis, aspergillosis, histoplasmosis, coccidioidomycosis, and others), viral (CMV, disseminated HSV, varicella-zoster virus [VZV]), or parasitic (toxoplasmosis, cryptosporidiosis, strongyloidiasis, isosporiasis, and *Acanthamoeba* infection). Mycobacteria (tuberculosis and atypical forms), *Salmonella*, *Treponema pallidum*, and *Staphylococcus aureus* are common causes of pulmonary and systemic bacterial infections. Many of these infections involve the central nervous system (CNS), secondarily in most cases, but sometimes as the primary infection. The papovavirus that causes progressive multifocal leukoencephalopathy (PML) infects brain primarily. Common pathogens in developing countries, such as *Trypanosoma*, are sometimes seen in recent immigrants to the United States.

Kaposi sarcoma, Hodgkin lymphoma, and non-Hodgkin lymphoma are the most commonly encountered neoplasms.

CNS PATHOGENESIS

HIV enters the CNS at the time of primary infection and may result in no apparent disease, acute self-limited syndromes, or chronic disorders. These are caused by HIV itself, secondary OIs, or neoplasia, metabolic abnormalities, medical treatment, or nutritional disorders. Neurologic disorders are found in up to 70% of patients with AIDS in clinical series and in more than 80% of autopsy series. In 10% to 20% of patients, the neurologic disorder is the first manifestation of AIDS. Uncommonly, a neurologic disorder is the sole evidence of chronic HIV infection and the cause of death. Early, effective antiretroviral treatment has decreased the incidence of secondary OI of the nervous system and may decrease the incidence of primary HIV-related syndromes.

Evidence of early CNS invasion includes isolation of virus from cerebrospinal fluid (CSF) or neural tissues (brain, spinal cord, peripheral nerve) and intrathecal production of antibodies to HIV. How HIV enters the CNS is not known. Possible mechanisms include intracellular transport across the blood-brain barrier within infected macrophages, free virus seeding the leptomeninges, or free virus after replication within the choroid plexus or vascular epithelium. In the brain, viral infection is detected only in microglial cells or macrophages by *in situ* hybridization techniques; it is not found in neurons or glial cells, even though these cells have CD4 and chemokine receptors.

The high frequency of neurologic disorders in HIV infection has led to the designation of HIV as a neurotropic virus. The term *neurotropic* implies selective vulnerability and homing of the virus to neurons. Alternatively, the high frequency of neurologic disorders may be explained by the chronicity of infection that results in continued seeding of the CNS. Specific neurotropism is not needed for continued accrual of neurologic damage. It has been difficult to establish correlation of neurologic syndromes with productive viral replication in the affected tissue. There is an increase, however, in the viral burden or viral load with advancing disease, which parallels dementia and other neurologic syndromes.

The mechanism of neurologic injury is believed to be indirect. Potential mechanisms include immune-mediated indirect injury; restricted persistent cellular infection; cellular injury due to cytokines released by infected monocytes and macrophages; excitotoxic amino acid injury; voltage-mediated increase of intracellular calcium; free radical damage; potentiation of inflammatory damage by chemokines and lipid inflammatory mediators (arachidonic acid and platelet activating factor); direct cellular toxicity of HIV gene products, such as the envelope glycoprotein gp120; and cross-reacting antibody to an HIV glycoprotein binding a cell membrane epitope, resulting in cell receptor blockade. More than one mechanism may be important. Genetic changes in the virus in the host may result in noncytopathic CNS virus with enhanced replicative capacity in monocytes and macrophages, leading to a greater viral burden in the CNS than is apparent in the periphery. Phenotypic and viral load discordance are documented in several studies of plasma and CSF. This compartmentalization of virus may explain the occurrence of neurologic syndromes when peripheral viral replication appears well controlled.

CLINICAL SYNDROMES

HIV-related Syndromes

Neurologic disorders may occur at any stage from first infection and seroconversion to AIDS. Even without other manifestations of HIV infection, some are diagnostic of AIDS (dementia and myelopathy). All levels of the neuraxis may be affected, including multisystem disorders. Neurologic disorders are likely to be transient in early HIV infection; in chronic infection, they are more prevalent and more often chronic or progressive.

The neurologic syndromes in early HIV infection are indistinguishable from disorders that occur with infection by other viruses ([Table 24.4](#)). These include aseptic meningitis, reversible encephalopathy, leukoencephalitis, seizures, transverse myelitis, cranial and peripheral neuropathy (Bell palsy, Guillain-Barré syndrome), polymyositis, and myoglobinuria. Brachial neuritis and ganglioneuritis are rarely reported. The course is typically self-limited and often with full neurologic recovery.

Acute aseptic meningitis
 Acute encephalopathy
 Leukoencephalitis
 Seizures, generalized or focal
 Transverse myelitis
 Cranial and peripheral neuropathy
 Bell palsy
 Acute inflammatory demyelinating polyneuropathy of the Guillain-Barré type
 Polymyositis
 Myoglobinuria

TABLE 24.4. PRIMARY HIV-RELATED NEUROLOGIC SYNDROMES: ACUTE INFECTION

CSF abnormalities (pleocytosis up to 200 cells/mm³ and oligoclonal bands) differentiate HIV syndromes from postinfectious disorders. Tests for HIV antibody may be negative because these syndromes may precede or accompany seroconversion, and the tests must be repeated in several weeks. If acute HIV infection is strongly suspected, p24 antigen and viral load assay should be considered if serology is negative. Early antiretroviral therapy may be offered to quickly lower the high viral load typical of acute infection, thereby lowering the viral load set point. The long-term efficacy of this approach is unknown. No specific treatment is indicated for these self-limited disorders, except that plasmapheresis or immune globulin is used for the Guillain-Barré syndrome and steroids for polymyositis.

In chronic HIV infection, neurologic disorders may accompany systemic HIV disease or secondary disorders ([Table 24.5](#)). Chronic or recurrent meningeal pleocytosis may occur, sometimes with meningeal symptoms, but it is often asymptomatic. Chronic pleocytosis does not predict any specific neurologic complication. Ascribing CSF pleocytosis to HIV infection requires exclusion of secondary pathogens or tumor.

Persistent or recurrent meningeal pleocytosis with or without meningeal symptoms
 Organic brain syndromes
 Dementia, static or progressive with or without motor signs
 Mild cognitive impairment, neuropsychologic test criteria only
 Organic psychiatric disorder
 Cerebrovascular syndromes
 Cerebellar ataxia
 Seizure disorder
 Multisystem degeneration
 Chronic progressive myelopathy
 Anterior horn cell disease
 Cranial and peripheral neuropathy
 Bell palsy
 Hearing loss
 Chronic inflammatory demyelinating polyneuropathy
 Distal symmetric sensory neuropathy
 Myeloneuritis multiplex
 Autonomic neuropathy
 Myopathy

From Britton CB, in: Rowland LP, ed. *Meritt's textbook of neurology*. Update 11. Philadelphia: Lea & Febiger, 1992; with permission.

TABLE 24.5. PRIMARY HIV-RELATED NEUROLOGIC SYNDROMES: CHRONIC INFECTION

Cognitive impairment is a well-recognized complication of chronic HIV infection; it may be mild or severe ([Table 24.6](#)). Mild cognitive impairment, detected by neuropsychologic tests, does not significantly impair daily function. Minor motor signs, usually motor slowness, may be present. Severe dementia, HIV-1-associated dementia complex (HADC), or AIDS dementia complex (ADC) is diagnostic of AIDS. Other designations are subacute encephalitis, subacute encephalopathy, or HIV encephalitis. The word *complex* is used to denote the association of dementia with motor and behavioral signs. Myelopathy and peripheral neuropathy coexist in 25% of patients.

Severe manifestations
 HIV-1-associated dementia complex
 HIV-1-associated myelopathy

Mild manifestations
 HIV-1-associated minor cognitive/motor disorder

From American Academy of Neurology AIDS Task Force, 1991; with permission.

TABLE 24.6. HIV-1-ASSOCIATED COGNITIVE/MOTOR COMPLEX AIDS DEMENTIA COMPLEX

HADC or ADC is an insidiously progressive subcortical dementia. Early symptoms include apathy, social withdrawal, diminished libido, slow thinking, poor concentration, and forgetfulness. Psychiatric syndromes are sometimes profound and may be the first manifestation of HIV infection, expressed as psychosis, depression, or mania. Motor signs include slow movements, leg weakness, and gait ataxia. There may be headache, tremor, seizures, parkinsonian features, or frontal release signs. Although the disorder is usually progressive, a static level of disability develops in some patients, and some improve in response to medical treatment for HIV or complicating disorders. Complete reversal is exceptional. When progressive, the disease culminates in akinetic mutism, an immobile, bedridden state with global cognitive impairment and urinary incontinence.

In children, there may be a similar static or progressive encephalopathy. Most affected children meet criteria for AIDS, but progressive encephalopathy may occur before immunologic dysfunction is severe, as in adults. Neurologic findings include intellectual deterioration, microcephaly, loss of developmental milestones, and progressive motor impairment that may culminate in spastic quadriplegia and pseudobulbar palsy. Seizures are usually due to fever. Myoclonus and extrapyramidal rigidity are rare.

The CSF is usually normal or shows mild pleocytosis, protein elevation, and oligoclonal bands. CSF gamma globulin content is increased owing to intrathecal synthesis of antibody to HIV antigens. Virus may be cultured from CSF. Both CSF and plasma viral load correlate with dementia occurrence but may be discordant in some cases, with the load being greater in CSF than in plasma. Phenotypic discordance is also observed, sometimes causing different patterns of drug resistance. CSF markers of immune activation may correlate with severity of dementia and include HIV p24 antigen, b₂-microglobulin, tumor necrosis factor, and antilysozyme protein. None of these is predictive of or specific for dementia. Other CSF and serum markers also lack predictive value or specificity but may correlate with severity of dementia; the list includes serum neopterin and tryptophan levels, CSF tryptophan and serotonin metabolites, and CSF quinolinic acid levels.

In adults, computed tomography (CT) or magnetic resonance imaging (MRI) may show cortical atrophy and ventricular dilatation, sometimes with white matter changes. On CT, there is attenuation of white matter; T2-weighted and proton-density MRI shows hyperintense white matter lesions ranging from discrete foci to large confluent periventricular lesions ([Fig. 24.1](#)). CT in children shows basal ganglia calcification and cerebral atrophy. MRI white matter changes may not correlate with dementia and may disappear spontaneously or with antiretroviral therapy.

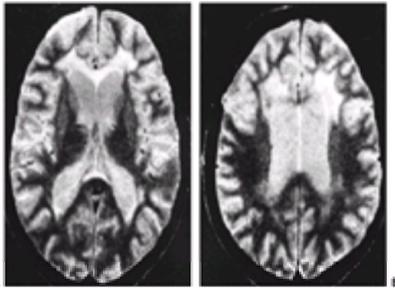

FIG. 24.1. A,B: T2-weighted MR images from a patient with progressive dementia show ventricular dilatation, cortical atrophy, and periventricular frontal lobe white matter hyperintensity.

Abnormalities in functional neuroimaging are detected in HIV-infected persons with and without dementia. The abnormalities become worse or change with progressive cognitive impairment. Positron emission tomography using fluorodeoxyglucose shows relative hypermetabolism in the thalamus and basal ganglia in HIV-infected persons. Progressive dementia is accompanied by cortical and subcortical hypometabolism. Single-photon emission computed tomography (SPECT) shows multifocal cortical perfusion deficits in the frontal lobes, which are worse in those with dementia. Cerebral metabolite abnormalities demonstrated by magnetic resonance spectroscopy (MRS) include elevated myoinositol and choline levels in frontal white matter, indicative of glial proliferation in patients with mild cognitive impairment. Severe dementia is associated with decreased levels of *N*-acetylaspartate, a neuronal marker. Dynamic cerebral blood volume (CBV) studies by functional MRI in HIV-positive persons show increased CBV in deep and cortical gray matter and even greater increases in deep gray matter of those with dementia.

Pathologic abnormalities in brain include microglial nodules, giant cells, focal perivascular demyelination and gliosis, and neuronal loss in the frontal cortex. There is often no correlation between the severity of pathologic changes and the severity of dementia.

The incidence of AIDS dementia is less than the frequency of pathologic abnormalities. The CDC reported a prevalence of 7.3% for the diagnosis of HIV encephalopathy in 1987 through 1991. The Multicenter AIDS Cohort Study Group reported a 4% prevalence of dementia diagnosis with a 7% annual rate and a 15% overall probability of dementia before death. There may be excess mortality in demented patients.

The diagnosis of HADC or ADC requires exclusion of secondary OIs or neoplasms. Other confounding variables include drug use and vitamin B₁₂ deficiency. Although some investigators report improvement in dementia and a lower incidence since the introduction of azidothymidine (zidovudine), others find transient or no effect of the drug on progressive dementia. The impact of protease inhibitors and HAART on dementia is not yet known. Clinical trials of selegiline hydrochloride (also known as deprenyl) (Eldepryl), a monoamine oxidase type B inhibitor, and nimodipine (Nimotop) suggest a trend for improvement in cognitive impairment. Antioxidants and agents that block gp120 are ineffective.

Longitudinal cohort studies have shown no neuropsychologic deterioration in asymptomatic individuals. Neuropsychologic test abnormalities do accrue with advancing disease but not necessarily with overt dementia. Those showing a decline in neuropsychologic test performance, however, have an excessive risk of death. The strongest predictors of significant dementia identified in a multiinstitution study of 19,462 HIV-infected persons are a CD4+ T-lymphocyte count of less than 100 cells/ μ L, anemia, and an AIDS-defining infection or neoplasm (18.6% to 24.9% risk in 2 years).

Stroke syndromes occur in 0.5% to 8% of patients in clinical studies, and infarcts are more frequent at autopsy. Stroke syndromes may follow secondary infections or neoplasms, such as cryptococcosis or other fungal infections, toxoplasmosis, tuberculosis, herpes zoster, CMV infection, syphilis, or Kaposi sarcoma. Other causes include HIV-related vasculitis, cardiogenic emboli, and thrombotic conditions such as hyperviscosity, disseminated intravascular coagulopathy, and lupus anticoagulant. Cerebral hemorrhage may follow HIV-associated thrombocytopenia or toxoplasmosis.

Evaluation of cerebrovascular syndromes includes imaging; CSF examination; cultures for viruses, bacteria, mycobacteria, and fungi; serum and CSF antibodies for cryptococcosis, syphilis, and toxoplasmosis; plasma and CSF HIV viral load; polymerase chain reaction (PCR) amplification of CSF for suspected pathogens; echocardiography; Doppler ultrasound; coagulation profiles; platelet count; and determination of procoagulants. If vasculitis is suspected, angiography or brain or meningeal biopsy may be useful.

Seizures may occur at any stage of HIV infection and may be focal or generalized. The incidence is uncertain, but in one study of 100 consecutive cases, secondary pathogens were identified in 53% and HIV encephalopathy in 24%; there was no identified cause in 23%. All patients with seizures should be evaluated for other pathogens or tumor.

Leukoencephalopathies in acute or chronic HIV infection include acute fulminating and fatal leukoencephalitis, multifocal vacuolar leukoencephalopathy presenting as rapid dementia, and a relapsing-remitting leukoencephalitis that may simulate multiple sclerosis. The pathogenesis of these syndromes is uncertain.

Chronic progressive myelopathy, an AIDS-defining illness, is characterized by progressive spastic, ataxic paraparesis with bowel and bladder disorders. Although most patients rapidly become wheelchair-bound, others progress indolently for years. Subclinical myelopathy may be detected by electrophysiologic studies in otherwise asymptomatic subjects. Pathologic findings are similar to those of subacute combined degeneration owing to vitamin B₁₂ deficiency and include vacuolar change with intramyelin swelling or demyelination that is most severe in the lateral and posterior columns. Microglial nodules and giant cells are sometimes seen, and HIV may be detected by hybridization techniques or cultured. Pathologic abnormalities are more commonly detected than clinical symptoms. The diagnosis of HIV myelopathy requires exclusion of cord compression, secondary infections, and nutritional deficiency. Contrast MRI may show gadolinium-enhanced lesions of myelitis.

No specific treatment is available for myelopathy. Improvement on zidovudine therapy has been reported, but the drug is generally ineffective. The impact of protease inhibitors and HAART is unknown.

Peripheral and autonomic neuropathy occur in otherwise asymptomatic HIV-infected persons, especially with advancing disease. Clinical syndromes include mononeuritis multiplex, chronic inflammatory demyelinating polyneuropathy (CIDP), distal symmetric polyneuropathy, and ganglioneuritis.

CIDP is distinguished from Guillain-Barré syndrome by a subacute or progressive course and variable response to steroids or plasmapheresis. Electrodiagnostic studies show demyelination with variable axonal damage. Histopathologic studies reveal epineurial inflammatory cell infiltrates and primary demyelination with variable axonal degeneration. HIV is sometimes cultured from nerve. CSF findings are nondiagnostic, although pleocytosis is sometimes found.

Distal sensorimotor neuropathy is the most common peripheral nerve disorder of AIDS, increasing in frequency with advancing disease. The incidence of neuropathy is also increasing because of longer survival of HIV-infected persons. Symptoms include painful, burning dysesthesia that is often confined to the soles of the feet. Signs include stocking-glove sensory loss, mild muscle wasting and weakness, and loss of ankle jerks. Conduction studies show sensorimotor neuropathy with mixed axonal and demyelinating features. Pathologic findings include axonal degeneration, loss of large myelinated fibers, and variable inflammatory cell infiltration. Vasculitis is sometimes found. CSF may be normal or show mild pleocytosis and elevated protein content. HIV may be cultured from nerve, but the cellular localization of the virus is not known. The neuropathy may be mediated by the binding of gp120 envelope viral glycoprotein to sensory ganglion cells.

The *pain syndrome* may be disabling, sometimes responsive to tricyclic antidepressants, anticonvulsants, and nonsteroidal or narcotic analgesia. Pain control may be difficult. Peptide T was ineffective in clinical trials. Immune globulin is sometimes used in refractory cases, with anecdotal reports of success. Vasculitis may respond to prednisone.

Myopathy is uncommon, characterized by proximal limb weakness, mild creatine kinase elevation, and myopathic features on electromyography (EMG). Pathologic findings include muscle fiber degeneration with or without inflammatory cell infiltrates. An HIV-related cause is suspected after exclusion of other causes. Zidovudine causes a clinically similar myopathy related to effects on mitochondria, with ragged red fibers. Cytochrome oxidase is deficient in zidovudine myopathy but not in HIV

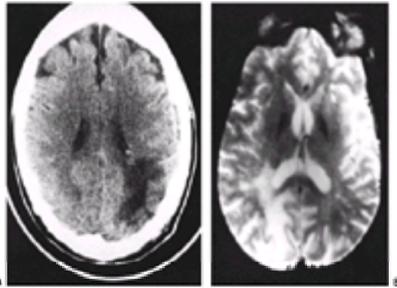

FIG. 24.3. A: CT in a patient with biopsy-proven PML shows a hypointense parietooccipital lesion without mass effect. **B:** T2-weighted MR image from a patient with biopsy-proven PML shows a hyperintense parietooccipital lesion.

There may be spontaneous stabilization of PML lesions in HIV infection, and there may be a response to zidovudine therapy or potent combination therapy that includes protease inhibitors. Clinical trials failed to show beneficial effect of intravenous or intrathecal cytarabine (Cytosar-U). There are anecdotal reports of efficacy, however. Topotecan, a topoisomerase inhibitor, is currently being studied.

Lymphoma is the most common neoplasm in AIDS, occurring in 0.6% to 3% of patients. Clinical signs are nonspecific and include focal neurologic signs, seizures, cranial neuropathy, and headache. CT may be normal or show hypodense lesions and single or multiple lesions with patchy or nodular enhancement. EBV DNA is found in PCR studies of CSF. Brain biopsy is required for diagnosis. The prognosis is poor; most patients succumb in 6 months. Some, however, respond to radiotherapy, chemotherapy, and management of coexistent OIs. There are reports of complete tumor regression after potent antiretroviral therapy. Other neoplasms reported in AIDS include metastatic Kaposi sarcoma and, rarely, primary glial tumors.

Movement disorders in patients with HIV infection are usually symptomatic of underlying cerebral infection, most commonly toxoplasmosis.

Infection of the spinal cord has been reported with the herpesvirus group, including HSV, CMV, and VZV, as well as with mycobacteria, pyogenic bacteria, and *Toxoplasma*. Spinal cord biopsy is necessary for definitive diagnosis and may be considered if systemic infection suggests metastatic foci in the spinal cord.

Infectious *retinopathy* may be caused by toxoplasmosis, CMV infection, or candidiasis. Cranial neuropathy may complicate meningitis. Polyradiculopathy or cauda equina syndrome may be due to CMV infection. The diagnosis may be suspected clinically in patients with disseminated CMV and may respond to ganciclovir sodium (Cytovene) and foscarnet sodium (Foscavir). Antiviral therapy may be given to patients with an otherwise typical syndrome, even before CMV infection is confirmed. PCR studies of CSF are helpful if positive, but negative studies do not exclude the diagnosis. Quantitative plasma PCR may identify persons at risk for CMV disease. Without treatment, the syndrome is progressive and fatal. Both the incidence and severity of CMV disease are lessened by HAART for HIV. In some cases, lifelong prophylaxis is no longer necessary. Pyomyositis may be due to infection with *S. aureus*, *Toxoplasma*, or atypical mycobacteria.

Drug-induced Syndromes

The nucleoside analogs used to treat HIV infection cause dose- and duration-related neurologic complications. Chronic zidovudine therapy may cause myopathy with ragged red fibers. Symptoms usually improve following cessation of the drug. The nucleoside antiretrovirals didanosine (ddI; Videx), zalcitabine (ddC; Hivid), stavudine (d4T; Zerit), and lamivudine (3TC; Epivir) can cause dose-related severe, painful sensory neuropathy that often improves after dose reduction or drug withdrawal. Failure to improve may indicate the cooccurrence of HIV-related neuropathy.

Patients with HIV infection experience hypersensitivity to many drugs, including the neuroleptics, which may cause secondary parkinsonism or the neuroleptic malignant syndrome. Nutritional deficiencies may include thiamine, vitamin B₁₂, folic acid, and glutathione, which may lead to encephalopathy, dementia, neuropathy, or spinal cord disorders. Metabolic abnormalities often occur in late disease and are reversible causes of encephalopathy.

DIAGNOSTIC EVALUATION

The diagnostic evaluation of patients with a suspected HIV-related disease includes an enzyme-linked immunosorbent assay for HIV serology. Positive results are confirmed by Western blot test. Depending on local laws, serologic tests may require informed consent and counseling. In patients with otherwise typical viral syndromes, such as aseptic meningitis or transverse myelitis, HIV infection must be suspected, even in the absence of known risk behavior. Absence of antibodies during the acute illness does not negate the diagnosis, because these disorders typically occur with seroconversion. A convalescent titer should be obtained at least 6 weeks later and possibly again at 3 and 6 months to ensure true seronegativity. Rarely, patients may be seronegative for prolonged periods. Repeat testing or studies to detect viral antigen or nucleic acid is based on risk behavior or other clinical information.

Other diagnostic studies include determination of CD lymphocyte subset ratio, plasma viral load, serum protein electrophoresis, quantitative immunoglobulins, and enumerated platelets. An anergy panel can assess functional immune status.

Evaluation for specific neurologic syndromes should be preceded by general physical examination to exclude OIs or tumor. Evaluation may include biopsy of skin, lymph nodes, or bone marrow, as well as chest film. Blood culture for viruses and fungi may be necessary. Accurate neurologic diagnosis requires systematic evaluation, including the possibility of multiple diseases. Electroencephalography may show evidence of a focal lesion when scans are still nondiagnostic. CSF is most helpful in syphilis and fungal or tuberculous infection. In lymphoma meningitis, tumor cells are rarely recognized by cytologic studies. Viruses are infrequently cultured from CSF; HIV may be detected but may be a copassenger and not responsible for the disorder in question. CMV may be cultured in CMV-related polyradiculopathy. PCR amplification of CSF may be helpful for diagnosis of CMV infection, toxoplasmosis, or PML; but negative results do not exclude these infections. CSF abnormalities are common in asymptomatic HIV infection and must be interpreted with caution in the consideration of other possible conditions. CT or MRI is useful in distinguishing focal from diffuse brain lesions. MRS and thallium-SPECT may distinguish tumor from infection.

Brain biopsy may be required for diagnosis. Stereotactic biopsy is a low-risk procedure in experienced hands. For solitary lesions, it is reasonable to treat for toxoplasmosis when serology or PCR is positive; biopsy is reserved for failure to respond to treatment and for PCR- and seronegative cases.

Myelopathy is evaluated by MRI with gadolinium enhancement or by myelography. CSF may be helpful in evaluating peripheral neuropathies, especially CMV polyneuropathy. EMG and nerve conduction studies are useful in evaluating myelopathy, peripheral neuropathy, and myopathy. Nerve or muscle biopsy may be required.

TREATMENT, COURSE, AND PROGNOSIS

Potent combination antiretroviral therapy has transformed AIDS from a fatal disease to a chronic illness. In the United States, AIDS diagnosis and AIDS deaths have declined since 1996. Even before potent drug therapy for HIV, prophylactic therapy of common OIs reduced their incidence. Improved medical care has reduced the need for hospital admissions in this population.

Antiretroviral drugs improve morbidity owing to HIV and extend survival. Fifteen drugs in three classes have been approved for use, and more are in clinical trials or development: nucleoside reverse transcriptase (RT) inhibitor, nonnucleoside RT inhibitor, nucleotide RT inhibitor, and protease inhibitor. Nucleoside RT inhibitors block viral replication by incorporation into the DNA copy of the RNA genome and termination of the DNA synthesis. This class includes zidovudine, didanosine, zalcitabine, stavudine, lamivudine, and abacavir (Ziagen). Nonnucleoside RT inhibitors include nevirapine (Viramune), delavirdine mesylate, and efavirenz (Sustiva). Adefovir dipivoxil is the sole nucleotide analog RT inhibitor. Protease inhibitors include ritonavir (Norvir), saquinavir mesylate (Invirase, Fortovase), indinavir

(Crixivan), nelfinavir (Viracept), and amprenavir. Combination drug therapy that includes a protease inhibitor is recommended.

Despite improved therapy, HIV infection is a serious diagnosis and rapidly fatal in developing countries, where there is no access to effective treatment. Moreover, therapy does not eliminate latent provirus and may fail if resistant mutants arise. Efforts continue in attempts to develop an effective vaccine. Candidate vaccines are in clinical trials in areas of high seroprevalence and seroconversion. The complex biology of the virus and the host immunogenetic response to infection pose significant challenges to successful vaccine development.

PRECAUTIONS FOR CLINICAL AND LABORATORY SERVICES

Strict observation of contamination procedures or universal precautions is mandatory. The hospital patient with known or suspected HIV infection is not isolated, unless there is a respiratory infection, such as tuberculosis, or severe neutropenia. Strict precautions should be observed in the handling of all waste, body fluids, and surgical specimens. Gloves are worn to prevent mucous membrane contact with blood, excretions, secretions, and tissues of infected patients. Goggles or glasses should be used if heavy aerosol contamination with blood or other secretions is anticipated, for example, in the operating room. Masks are not needed, unless the patient requires respiratory isolation for other reasons. Needles and other sharp instruments in contact with infected blood should be disposed in proper containers. Health care workers should not recap needles to avoid needle-stick injury.

The risks to health care workers are small but real. At least 52 people have been documented with HIV seroconversion following needle-stick injury or mucocutaneous exposure. The converse risk, to patients from infected workers, is exceedingly small, but HIV-positive workers should not engage in invasive procedures in which cuts may occur.

HIV is readily inactivated by heat in standard sterilization solutions including 70% alcohol. Special sterilization procedures may not be necessary but are often used.

HIV-infected people may survive 10 to 20 years or longer before succumbing. During this time, many complications are likely to ensue. Patients need rigorous evaluation for systemic and neurologic syndromes at all stages of infection because of the risk for multiple, coexistent, or sequential problems.

CHAPTER 25. FUNGAL AND YEAST INFECTIONS

LEON D. PROCKOP

[Cryptococcosis](#)
[Mucormycosis](#)
[Suggested Readings](#)

Fungal infection, or mycosis, of the central nervous system (CNS) results in one or more of the following tissue reactions: meningitis, meningoencephalitis, abscess or granuloma formation, or arterial thrombosis. Subacute or chronic meningitis and meningoencephalitis are most common, but granulomatous lesions and abscesses typify the response to some fungi; thrombotic occlusions occur with other fungal infections. The lungs, skin, and hair are usually the primary sites of involvement by fungi.

Fungi exist in two forms: molds and yeasts. *Molds* are composed of tubular filaments called hyphae that are sometimes branched. *Yeasts* are unicellular organisms that have a thick cell wall surrounded by a well-defined capsule. Infecting fungi comprise two groups: pathogenic and opportunistic.

The *pathogenic* fungi are those few species that can infect a normal host after inhalation or implantation of the spores. Naturally, chronically ill or other immunologically compromised persons are more susceptible to infection than normal persons. Acquired immunodeficiency syndrome (AIDS) has become a major cause of fungal infection. In nature, fungi grow as saprophytic soil-inhabiting mycelial units that bear spores. During infection, they adapt to higher temperatures and lower oxidation-reduction potentials of tissues. They also overcome host defenses by increased growth rate and by relative insensitivity to host defense mechanisms (e.g., phagocytosis).

The pathogenic fungi cause histoplasmosis, blastomycosis, coccidioidomycosis, and paracoccidioidomycosis. The first three are endemic to some areas of North America, and the last is endemic to areas of Central and South America. Neurologic disorders are rare in patients with systemic North American blastomycosis or histoplasmosis. Coccidioidomycosis is a more common disease, especially in Arizona and California, and meningitis is a dreaded, often fatal complication.

The second group of systemically infecting fungi, the *opportunistic* organisms, is not thought to incite infection in the normal host. Diseases include aspergillosis, candidiasis, cryptococcosis, mucormycosis (phycomycosis), nocardiosis, and even rarer fungal diseases. With some of these fungi, minor changes in host defenses may cause disease (e.g., candidal overgrowth in mucous membranes). With most opportunistic fungi, the CNS is infected only after major changes have occurred in the host, such as extensive use of antimicrobial agents that destroy normal nonpathogenic bacterial flora, administration of immunosuppressive agents or corticosteroids that lower host resistance, and existence of systemic illness, such as Hodgkin disease, leukemia, diabetes mellitus, AIDS, or other diseases that interfere with immune responses of the host. Prolonged therapeutic use of deep venous lines also seems to be a contributing factor.

Except in some regions of Asia, CNS manifestations of aspergillosis are uncommon. CNS nocardiosis is rare. Although clinically apparent meningeal infection with candidae is rare, candidiasis has become an increasingly common postmortem brain finding, although it is not often revealed clinically. In autopsy studies, candidiasis occurs in compromised patients and produces intracerebral microabscesses and noncaseating granulomas without diffuse leptomeningitis. In contrast to most mycoses, in which neurologic disease is secondary to systemic involvement, cryptococcal meningitis may be a primary infection. Although this fungus is considered opportunistic, the factors that predispose to cryptococcal infection in some apparently normal individuals are unknown.

In mucormycosis, primary infection of the nasal sinuses and eye often extends to the brain or cranial nerves in the compromised patient. Rare fungal causes of neurologic disorders include altescheriosis, alternariasis, cephalosporiosis, cladosporiosis, diplorhinotrichosis, drechsleriiasis, fonsecaeasis, madurellosis, paecilomycosis, penicilliosis, sporotrichosis, streptomycosis, torulopsosis, trichophytosis, and ustilagomycosis.

Diagnosis of fungal infections is often difficult and depends on the alertness of the physician. The characteristic findings in radiographs of the lungs and other organs, skin tests, antibody tests of serum and CSF, and isolation of organisms from lesions and CSF are important diagnostic aids. Serial monitoring of serum antigen (e.g., *Aspergillus*) shows promise in early diagnosis. Brain computed tomography (CT) and magnetic resonance imaging (MRI) may document mass lesions caused by granulomas or abscess. Likewise, in meningitis, CT or MRI may demonstrate obliteration of subarachnoid spaces or hydrocephalus, findings that are useful in management and prognosis.

Treatment of human fungal infections is at best unsatisfactory. Penicillin and other commonly used antimicrobial agents are useless and may lead to spread of the infection, except in actinomycosis or nocardiosis. Actinomycosis is curable by either tetracycline antibiotics or penicillin, and nocardiosis responds to sulfonamides. Amphotericin B is the most effective therapeutic preparation for most neurologic fungal disease, although important roles for miconazole, ketoconazole (Nizoral), fluconazole (Diflucan), and itraconazole (Sporanox) are being recognized.

CRYPTOCOCCOSIS

Cryptococcosis is the most common mycotic infection that directly involves the CNS and is a major cause of morbidity and mortality among immunosuppressed patients. The disease may simulate tuberculous meningitis, brain tumor, encephalitis, or psychosis.

Pathogenesis

Cryptococcus neoformans (*Torula histolytica* or *Torulopsis neoformans*) is a fungus found throughout the world. Infections by the small yeastlike spherule have been described under various terms such as torulosis, yeast meningitis, and European blastomycosis. Although the skin and mucous membranes may be the primary sites of infection, the respiratory tract is usually the portal of entry. The organism has been recovered in fruit, milk, soil, wasps' nests, some grasses and plants, human skin and mucous membranes, and the manure of pigeons and other birds. The manure serves as a reservoir from which human infection may occur.

In 30% to 60% of reported cases, cryptococcosis is associated with debilitating diseases, such as AIDS, lymphosarcoma, reticulum-cell sarcoma, leukemia, Hodgkin disease, multiple myeloma, sarcoidosis, tuberculosis, diabetes mellitus, renal disease, and lupus erythematosus. CNS infection may occur independently of, or in association with, systemic disease. By the time the diagnosis of systemic cryptococcosis is firmly established, however, 70% of patients have neurologic abnormalities.

Pathology

The changes in the nervous system include infiltration of the meninges by mononuclear cells and cryptococcal organisms. The organisms may be scattered diffusely throughout the parenchyma of the brain with little or no local inflammatory reaction. Occasionally, an abscess or small granulomas form in the meninges of the brain or spinal cord.

Symptoms and Signs

Symptomatic onset of nervous system involvement is subacute. Meningeal symptoms usually predominate, but occasionally focal neurologic signs or mental symptoms are in the foreground. The usual clinical picture is that of subacute meningitis or encephalitis. The diagnosis of tuberculous meningitis is often entertained until the correct diagnosis is revealed by the peculiar appearance of some of the "cells" in the CSF. The diagnosis of yeast meningitis can be established by culture of the organism on Sabouraud medium.

Large granulomas in the cerebrum, cerebellum, or brainstem cause the same clinical syndromes as do other expanding lesions in these sites. Before the availability of CT and MRI, the diagnosis of a granuloma was rarely made before operation. Nonetheless, definitive diagnosis can be made only when meningeal involvement is

also present and organisms are recovered from the CSF.

Laboratory Data

The CSF findings in infections with cryptococci are similar to those of tuberculous meningitis. The CSF is usually under increased pressure. There is a slight or moderate pleocytosis of 10 to 500 cells/mm³. The protein content is increased. The sugar content is decreased, with values commonly between 15 and 35 mg/dL. The diagnosis is made by finding the organisms in the counting-chamber centrifuge sediment of the fluid (Fig. 25.1), by growth on Sabouraud medium, or by the results of animal inoculation. The organisms also may be cultured from the urine, blood, stool, sputum, and bone marrow. They are usually visible on smear or growth in cultures. Diagnosis can be established by the detection of cryptococcal antigen in serum and CSF.

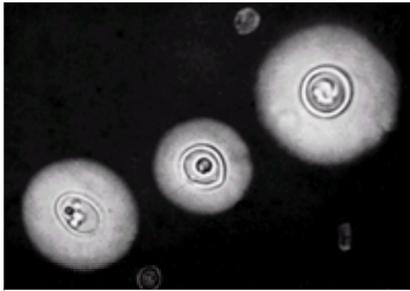

FIG. 25.1. *Cryptococcus neoformans* meningitis. Fresh preparation of sediment from CSF stained with India ink. The capsule is three times the diameter of the cell. (Courtesy of Dr. Margarita Silva.)

Course

The disease in untreated patients is usually fatal within a few months, but occasionally it persists for several years with recurrent remissions and exacerbations (Fig. 25.2). Occasionally, yeast organisms in the CSF have been noted for 3 years or longer. Spontaneous cure has been reported in a few cases.

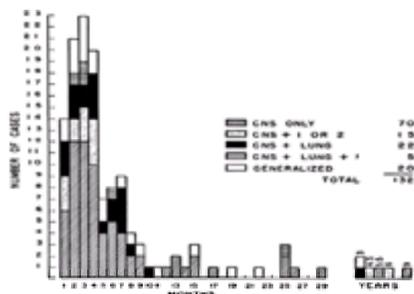

FIG. 25.2. Duration of life (in months) for 132 patients with untreated cryptococcal meningitis, from onset to death. *Stippled areas 1 and 2* indicate cases in which skin or bones were also involved. (Courtesy of Dr. Charles Carton.)

Treatment

Treatment with amphotericin B has a definite beneficial effect. Butler and associates reported improvement in 31 of 36 treated patients. Of the 31 patients who showed improvement, 17 remained well, three died of unrelated causes, and 11 had one or more relapses of meningitis. In this era of epidemic AIDS, cryptococcosis is reported even more frequently. Many authorities now consider fluconazole to be the drug of choice for AIDS-associated cryptococcal infection. Fluconazole should be continued for 3 months after the CSF is sterilized. Suppressive therapy with 200 mg orally once daily is employed in relapsing cases. Liver function studies must be monitored if phenytoin sodium (Dilantin) is given concomitantly.

Alternative therapy employs amphotericin B and flucytosine (Ancobon). Combined treatment may be used to prevent failure resulting from emergence of flucytosine resistance. Amphotericin B has sometimes been given by cisternal injection or by administration into the lateral ventricle through an Ommaya reservoir. Sterility of the CSF is probably the best endpoint of successful treatment. The course of treatment should be repeated if a relapse occurs.

Side effects of amphotericin B include thrombophlebitis, nausea and vomiting, fever, anemia, hypokalemia, and elevation of the blood urea level. Aspirin and antihistamines, blood transfusions, and temporary reduction in the drug dosage are of value in control of side effects.

MUCORMYCOSIS

Cerebral mucormycosis (phycomycosis) is an acute, rarely curable disease caused by fungi of the class Phycomycetes, especially of the genus *Rhizopus*. A common contaminant of laboratory cultures, it is not ordinarily pathogenic. Cases have been reported in all parts of the United States, in Canada, and in England. The disease probably exists worldwide. It usually occurs as a complication of diabetes mellitus or a blood dyscrasia, particularly leukemia. Use of antibiotics and adrenocortical steroids may also predispose patients to mucormycosis.

The fungi enter the nose and, in susceptible persons, cause sinusitis and orbital cellulitis. Subsequently, they may penetrate arteries to produce thrombosis of the ophthalmic and internal carotid arteries, and may later invade veins and lymphatics. Ocular, cerebral, pulmonary, intestinal, and disseminated forms of the disease exist.

Proptosis, ocular palsies, and hemiplegia are common neurologic signs associated with the involvement of the orbital and internal carotid arteries. The organisms may invade the meninges to cause meningitis or may extend into the brain to produce a mycotic encephalitis.

Diagnosis is made by examination of the sputum, CSF, or exudate of tissue from the nasal sinuses. Culture of *Rhizopus* is corroborative but not diagnostic because it is a common contaminant.

A dramatic improvement in prognosis has been noted in recent years, with 73% survival of patients diagnosed since 1970 compared to 6% survival before 1970. Treatment consists of the administration of amphotericin B and control of predisposing factors (e.g., diabetes). Local drainage and early surgery of the necrotic tissue should be performed to prevent spread of disease.

CHAPTER 26. NEUROSARCOIDOSIS

JOHN C.M. BRUST

[Suggested Readings](#)

Sarcoidosis is a multisystem granulomatous disease of unknown cause. Sarcoid granulomas resemble those of tuberculosis but lack tubercle bacilli, caseation, or characteristic necrosis. Active lesions contain epithelioid and multinucleate giant cells; such lesions may resolve but more often become fibrotic.

Sarcoidosis occurs worldwide, with estimated prevalence ranging from 3 to 50 per 100,000 population. In the United States, it occurs more frequently in blacks. Onset is most often in the fourth or fifth decade, but the disease also affects children and the elderly. An infectious cause remains elusive. Immunologic features include concentration at disease sites of activated CD4 lymphocytes, which secrete cytokines that in turn lead to accumulation of monocytes and macrophages to form granulomas. Lesions can affect any organ, especially lung, lymph nodes, skin, bone, eyes, and salivary glands. The nervous system is clinically involved in about 5% of patients, one-half of whom have central or peripheral nervous system disease at presentation. Although nearly 20% of such patients have only neurologic symptoms or signs, workup reveals evidence of systemic disease in as many as 97%. When nervous system disease complicates systemic sarcoidosis, it usually does so within 2 years of onset.

In the central nervous system (CNS), sarcoid granulomas most often involve the meninges, especially at the base of the brain, with secondary infiltration of cranial nerves and obstruction of CSF flow. Lesions tend to be perivascular and thereby can spread intraparenchymally, thus frequently affecting the hypothalamus and less often other CNS structures, including the spinal cord. Granulomas also occur in peripheral nerves and muscle.

Given the unpredictable dispersal of lesions, sarcoidosis is a clinically protean disease, systemically and neurologically. Nearly 50% of patients with neurosarcoidosis have more than one neurologic complication, with relative frequencies varying among different clinical series ([Table 26.1](#)).

Cranial neuropathy	53% (range, 37%-73%)
CNS parenchymal disease	48% (range, 14%-100%)
Aseptic meningitis	22% (range, 8%-40%)
Peripheral neuropathy	17% (range, 6%-40%)
Myopathy	15% (range, 7%-26%)
Hydrocephalus	7% (range, 0-14%)

TABLE 26.1. SYMPTOMS AND SIGNS IN NEUROSARCOIDOSIS

Although any cranial nerve can be affected, the most frequently affected is the seventh, sometimes in association with uveitis and parotitis (uveoparotid fever) but usually alone, thus suggesting Bell palsy. Facial weakness can be bilateral and either simultaneous or sequential, and can recur after recovery. Optic nerve involvement causes papillitis or retrobulbar neuritis and eventually optic atrophy. Trigeminal nerve involvement causes either sensory loss or neuralgia, and eighth cranial nerve lesions produce auditory and vestibular symptoms.

Granulomas involve the hypothalamus more often than the pituitary, thereby producing combinations of endocrinologic and nonendocrinologic symptoms that include diabetes insipidus, decreased libido, galactorrhea, amenorrhea, abnormal sleep patterns, altered appetite, temperature dysregulation, and abnormal behavior. Cerebral granulomas may be scattered diffusely, some too small to be detected on computed tomography (CT) or magnetic resonance imaging (MRI), or they may consist of one or more large masses that mimic a brain neoplasm. Seizures are common in such patients. Symptomatic subdural granulomas have occurred. Rarely, sarcoid vasculitis causes cerebral infarction in a pattern clinically and pathologically indistinguishable from so-called granulomatous angiitis of the nervous system. Autoantibodies to endothelial cells have been identified in patients with neurosarcoid.

Meningeal infiltration can be asymptomatic or produce symptomatic aseptic meningitis. Complications include cauda equina signs, hydrocephalus, and ependymitis with encephalopathy.

Peripheral nerve lesions cause mononeuropathy, mononeuropathy multiplex, and sensory, motor, or sensorimotor polyneuropathy, either chronically progressive or resembling Guillain-Barré neuropathy. A positive muscle biopsy has been reported in as many as 75% of patients with sarcoidosis. However, muscle granulomas are usually asymptomatic, although they sometimes cause palpable nodules or progressive diffuse polymyositis.

In patients known to have sarcoidosis, the appearance of neurologic symptoms usually poses no diagnostic problem, but the possibility of unrelated disease must be kept in mind, especially potential complications of corticosteroid treatment such as infection (tuberculosis, mycosis, toxoplasmosis, or progressive multifocal leukoencephalopathy), mental change, or myopathy. Patients with neurologic symptoms require both systemic and neurologic investigation. CNS granulomas, symptomatic or asymptomatic, are apparent on either T2-weighted MRI or contrast-enhanced CT; they are sometimes calcified. Leptomeningeal CT enhancement is common, and imaging can reveal hydrocephalus and spinal cord, cauda equina, or optic nerve involvement. The CSF may contain as many as a few thousand white cells (usually with lymphocytic preponderance), elevated protein levels, and low sugar content, as well as elevated immunoglobulin (Ig) G and IgG index, oligoclonal bands, and elevated angiotensin-converting enzyme (ACE) (also found in infection and malignancy).

Other studies, tailored to individual patients, include chest radiographs (revealing either asymptomatic hilar adenopathy or, more ominously, fibronodular disease), pulmonary function studies, bronchiolar lavage for lymphocytes, serum calcium (elevated in about 20% of patients with sarcoidosis), urinary calcium (elevated in 50%), serum ACE (elevated in 65%), serum gamma globulin (elevated in 50%), serum sodium, and endocrinologic studies (thyroid function tests, cortisol, gonadotropins, testosterone or estradiol, and prolactin). About two-thirds of patients are anergic to tuberculin purified protein derivative, mumps, and other antigens, and those who are positive are usually only weakly so. Ophthalmologic or otolaryngologic consultation may disclose unsuspected lesions. Systemic or brain gallium scanning can be positive but is nonspecific. Diagnosis ultimately depends on histology; biopsy sites include lymph nodes (including transbronchial), salivary gland, conjunctiva, skin, liver, and, as a last resort, meninges or brain. Kveim testing can be diagnostic, but the antigen, unavailable in many centers and not well standardized, is not approved by the U.S. Food and Drug Administration for general use.

About two-thirds of patients with neurosarcoidosis have a self-limited monophasic illness; the rest have a chronic remitting-relapsing course. With treatment, death from neurologic disease is unusual. Although controlled studies are lacking, corticosteroids appear to reduce symptoms and size of granulomas, and it is unclear whether they affect the natural history. Their use depends on the clinical setting. Short-term therapy can be given to patients with aseptic meningitis or isolated facial palsy; long-term treatment is often necessary for intraparenchymal lesions, hydrocephalus, optic or other cranial nerve involvement, peripheral neuropathy, or symptomatic myopathy. Prednisone, 40 to 80 mg daily, can be given for a few weeks and then slowly tapered either to a lowest possible maintenance dose or, if possible, to discontinuation. Higher initial doses may be necessary in some patients. Adjunctive immunosuppressive treatment for refractory patients includes azathioprine (Imuran), methotrexate, cyclophosphamide, chlorambucil (Leukeran), and cyclosporine (Sandimmune). Radiation therapy has been used with uncertain benefit.

DEFINITION

Neurosyphilis comprises several different syndromes that result from infection of the brain, meninges, or spinal cord by *Treponema pallidum* (Table 27.1). It is not known how much damage is caused by direct effects of the organism and how much by other immune mechanisms.

Type	Clinical Syndrome	Pathology	CSF WBC	WBC of CSF or RBC
1. Asymptomatic	No symptoms, CSF abnormal	Normal, CSF, but positive treponemal antibody	<5	None
A. Meningeal and vascular (meningovascular)	General paresis	Leptomeningitis with perivascular degeneration of cerebral cortex, and diffuse leukoencephalopathy	Absent	None
	Tabes dorsalis	Leptomeningitis with degeneration of posterior horns of spinal cord	Absent	None
	General paresis and tabes dorsalis	Leptomeningitis with degeneration of posterior horns of spinal cord and cerebral cortex	Absent	None
	General paresis and tabes dorsalis	Leptomeningitis with degeneration of posterior horns of spinal cord and cerebral cortex	Absent	None
B. Parenchymal (tabes)	General paresis	Leptomeningitis and perivascular degeneration of cerebral cortex	Absent	None
	Tabes dorsalis	Leptomeningitis and degeneration of posterior horns of spinal cord	Absent	None
C. Focal (parenchymal)	General paresis	Leptomeningitis and perivascular degeneration of cerebral cortex	Absent	None
	Tabes dorsalis	Leptomeningitis and degeneration of posterior horns of spinal cord	Absent	None

TABLE 27.1. CLASIFICATION OF NEUROSYPHILIS

A clinical definition must include the results of diagnostic laboratory tests. Accordingly, neurosyphilis is defined by three findings: a syndrome consistent with neurosyphilis, abnormal blood titer of a treponemal antibody test, and positive nontreponemal antibody test in the cerebrospinal fluid (CSF). All three must be present.

HISTORY

Neurosyphilis, recognized for about 100 years, has played an important role in the evolution of modern neurology. Paretic neurosyphilis was the first “mental disorder” for which specific cerebral pathology was found. Erb described spinal syphilis (tabes dorsalis) in 1892. Quincke introduced lumbar puncture, and CSF examination was used to diagnose infection, even in asymptomatic people. The organism was identified in the brain by Noguchi and Moore in 1913. The first effective treatment came in 1918 when Wagner Jaurregg gave fever therapy for paresis. He was the first neurologist to be given a Nobel Prize. Then came arsenical chemotherapy, the first planned use of a drug that would attack the organism without harming host tissues; this was Ehrlich’s concept of “the magic bullet.” Safer and more effective therapy came in 1945 with the introduction of penicillin, which has been used since.

Syphilis was also important in the evolution of this textbook. The subject has been allotted many pages because the disease was a major research interest of Houston Merritt and it was still prevalent when he wrote the first edition. His chapters were revised only slightly in subsequent editions, but now neurosyphilis is inextricably linked to acquired immunodeficiency syndrome (AIDS). Classic clinical syndromes are now exceptional, and both diagnosis and therapy have become more complicated; these changes require a recasting of the description.

EPIDEMIOLOGY

Following the introduction of penicillin, the incidence of neurosyphilis declined for two main reasons: (1) Fewer people spread the disease because those affected were being identified and treated, and (2) many neurosyphilitic infections were prevented because penicillin was being used to treat gonorrhea and other infections. For instance, the frequency of neurosyphilis as a cause of first admission to a psychiatric hospital plummeted from 5.9 per 100,000 population in 1942 to 0.1 per 100,000 in 1965. New cases became so rare that many hospitals discarded routine testing to detect syphilis.

During the next few decades, some investigators detected a shift in the clinical patterns, but this finding was debated. The segment of the population with the highest incidence was young homosexual men. Then, in 1981, came AIDS. The incidence of primary and secondary syphilis rose from 13.7 per 100,000 in 1981 to 18.4 per 100,000 in 1989, an increase of 34%. Between 1985 and 1989, the increase was 61%. Since then, there has been further decline in the incidence of syphilis. In 1997, fewer than 8,000 cases of early syphilis were reported in the United States, representing the lowest rates in 38 years and a sixfold decline since 1990.

Neurosyphilis ultimately develops in about 10% of untreated persons with early syphilis. Among those infected with human immunodeficiency virus (HIV), about 15% have serologic evidence of syphilis, and about 1% have neurosyphilis.

Even before the HIV era, there had been a shift in clinical manifestations because of the widespread use of antibiotics. Previously common parenchymal forms became rare, while the incidence of meningeal and vascular syndromes rose (Table 27.2). The diagnosis of neurosyphilis is often delayed because there are other, more common causes of stroke and meningitis. From 1985 to 1992 in San Francisco, parenchymal forms of neurosyphilis accounted for only 5% of 117 cases.

	Preantibiotic Era (%)			Antibiotic Era (%)			AIDS Era (%)	
	1	2	3	4	5	6	7	8
Tabetic	45	48	45	15	11	5	5	8
Paretic	17	18	8	12	6	9	4	4
Taboparetic	4	7	9	23	20	—	—	—
Vascular	15	19	9	19	31	41	38	38
Meningeal	8	8	19	23	8	23	46	46
Optic neuritis	4	—	—	—	—	34	42	42
Spinal cord	4	—	19	8	—	—	—	—

TABLE 27.2. FREQUENCY OF DIFFERENT FORMS OF SYMPTOMATIC NEUROSYPHILIS*

PATHOLOGY

In early neurosyphilis, lymphocytes and other mononuclear cells infiltrate the meninges. The inflammatory reaction also involves the cranial nerves and provokes axonal degeneration. When the inflammation affects small meningeal vessels, occlusion due to endothelial proliferation may lead to ischemic necrosis of brain and spinal cord. This process may cause demyelination, myelomalacia at the periphery of the cord, or transverse myelitis.

The pathology of dementia paralytica develops slowly. After an inflammatory meningeal reaction, lymphocytes and plasma cells infiltrate small cortical vessels and sometimes extend into the cortex itself. The cortical inflammatory response provokes loss of cortical neurons and glial proliferation. Spirochetes can be demonstrated in the cortex in dementia paralytica, but only rarely in other forms of neurosyphilis.

In tabes dorsalis, the mononuclear inflammation of meninges and blood vessels is followed by insidious degeneration of the posterior roots and posterior fiber columns of the spinal cord ([Fig. 27.1](#)), as well as the cranial nerves occasionally.

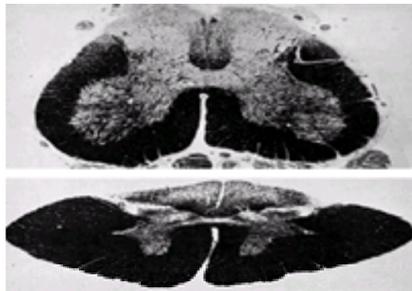

FIG. 27.1. Tabes dorsalis. Degeneration of the posterior column in the sacral and thoracic cord (myelin sheath stain). (From Merritt et al., 1946.)

CLINICAL DIAGNOSIS

The three most common forms of neurosyphilis are asymptomatic, meningeal, and vascular. Often, the meninges and cerebral vessels are affected together in meningovascular neurosyphilis. The once prominent parenchymal forms, including general paresis (dementia paralytica) and tabes dorsalis, are rarely seen now. The major clinical syndromes are differentiated from other causes of the same manifestations only by finding blood and CSF changes indicative of syphilis. Of course, the patient with serologic evidence of syphilis and concomitant HIV or other viral meningitis poses a diagnostic dilemma. Therefore, the efficacy of diagnostic tests must be considered.

Serology

Isolation of *T. pallidum* is difficult and impractical for clinical diagnosis, which rests on two categories of antibodies that are used as serologic tests for syphilis (STS). *Nontreponemal* antibodies react with reagin, a complex of cardiolipin, lecithin, and cholesterol. This complex was the basis for the original complement-fixation Wasserman test, for the more sensitive Kolmer test, and then for the Venereal Disease Research Laboratory (VDRL) test and a variation called the rapid plasma reagin (RPR) test, a flocculation test that is macroscopically visible on a glass slide. The RPR test is not suitable for CSF.

The CSF VDRL test is highly specific, but false-positive reactions can result from contamination of CSF by blood, high CSF protein content, or the presence of paraproteinemia or autoimmune disease. Some clinicians believe that the CSF VDRL test may be negative in some cases of neurosyphilis, but if so, the clinical syndrome of neurosyphilis would then be difficult to prove, especially if the manifestations were not typical. Although accurate in diagnosis, the CSF VDRL test is not as reliable in following treatment (because the titer may not change); CSF pleocytosis is a more useful guide.

An even more specific treponemal antibody test is the *fluorescent treponemal antibody (FTA)* test. The antigen preparation is made from the spirochete and can be absorbed (FTA-ABS) to remove sources of nonspecific and false reactions. A positive FTA-ABS test in plasma has high specificity for diagnosis, but not for activity because it may remain positive for years after successful treatment. In addition, the test is so sensitive that it cannot be used on CSF because as little as 0.8 μL blood in 1 mL CSF can give a positive reaction. A diagnosis of syphilis requires a high titer in the blood on VDRL testing, ascertained by a positive FTA-ABS. In some centers, a variation of the FTA is the *microhemagglutination test* for *T. pallidum*.

Problems arise when the specific treponemal tests are applied to CSF. They lack specificity because positive results appear with minor contamination by blood or with diffusion of serum immunoglobulins into CSF. Attempts to increase the reliability have included indices of intrathecal production (intrathecal *T. pallidum* antibody and *T. pallidum* hemagglutination assay); still it is difficult to be confident of the diagnosis of neurosyphilis if other CSF measures are normal. The specific treponemal antibody tests for CSF are more reliable in excluding neurosyphilis than in confirming it.

Another promising technique is the polymerase chain reaction that amplifies treponemal deoxyribonucleic acid in CSF. However, the test is not yet fully developed.

Therefore, the diagnosis of neurosyphilis requires appropriate blood serology and a reactive CSF VDRL test, which is also a measure of disease activity. A reactive FTA-ABS in the blood indicates that the CSF VDRL result is not a false-positive.

CSF Abnormalities

CSF pleocytosis is the best measure of disease activity, and the number of cells is roughly proportionate to the clinical syndrome. In an untreated patient, the white blood cell (WBC) count should be at least 5 cells/mm³ for secure diagnosis. The pleocytosis should respond to penicillin therapy within 12 weeks. The CSF protein content is usually increased, and the sugar content may be low or normal. The CSF content of gamma globulin may be increased and oligoclonal bands may be present, but these findings are nonspecific.

CLINICAL SYNDROMES

In the following discussion of clinical syndromes, we assume positive VDRL or FTA-ABS in serum, positive CSF VDRL, and CSF pleocytosis. These findings constitute the modern diagnostic triad of neurosyphilis, even in HIV-positive patients.

Asymptomatic Neurosyphilis

This diagnosis depends entirely on the serologic findings in blood and CSF. If there are more than 5 WBCs/mm³, the disorder could be called "asymptomatic meningeal syphilis," and there may be meningeal enhancement on MRI.

Meningeal Neurosyphilis

This syndrome is seen within a year of the primary infection. The clinical manifestations are those of any acute viral or aseptic meningitis: malaise, fever, stiff neck, and headache. The CSF cell count may rise to several hundred, CSF pressure may be increased, and CSF glucose may be low but is usually greater than 25 mg/dL. The protein content may exceed 100 mg/dL. The syndrome may subside spontaneously and is recognized by positive blood and CSF STS reactions.

Signs may not appear on examination, or there may be cranial nerve abnormalities, with facial diplegia or hearing loss. Occlusion of CSF pathways may cause obstructive or communicating hydrocephalus, and the course may be punctuated by cerebral infarction (meningovascular lues).

Cerebrovascular Neurosyphilis

Cerebral infarct syndromes of syphilis are similar to those of other, more common causes; the diagnosis rests on typical findings in blood and CSF. Patients are younger than those with atherosclerosis and are more likely to have risk factors for venereal disease. Clinical evidence may imply concomitant meningeal disease (meningovascular disease), with a prodromal syndrome of headache or personality change for weeks before the ictus, and signs may progress for several days. MRI may show meningeal enhancement. Symptoms appear 5 to 30 years after the primary infection.

Meningovascular Syphilis of the Spinal Cord

Conventional symptoms and signs of transverse myelitis (meningomyelitis) usually affect both sensory and motor pathways, as well as bladder control. The syndrome must be differentiated from tabes, a parenchymal infection. Syphilis has not reliably been implicated as a cause of motor neuron disease, and it is doubted that syphilis ever causes "spastic paraplegia of Erb," an anterior spinal artery syndrome.

Gumma

This mass lesion is now rare. This avascular granuloma was attached to the dura and was considered a localized form of meningeal syphilis.

Paretic Neurosyphilis

This form of neurosyphilis has also been called dementia paralytica, general paresis of the insane, or syphilitic meningoencephalitis. Spirochetes cause the chronic meningoencephalitis. The leptomeninges are opalescent to opaque, thickened, and adherent to the cortex; the cortical gyri are atrophic (Fig. 27.2). The sulci are widened and filled with CSF. When the brain is sectioned, the ventricles are enlarged. The walls are covered with sandlike granulations termed *granular ependymitis* (Fig. 27.3).

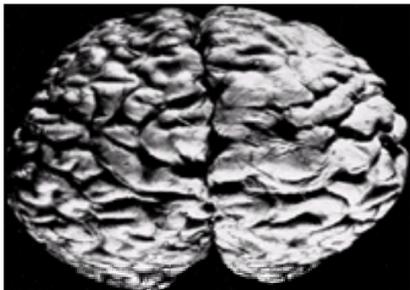

FIG. 27.2. Paretic neurosyphilis. Thickening of the meninges and atrophy of the cerebral convolutions. (From Merritt et al., 1946.)

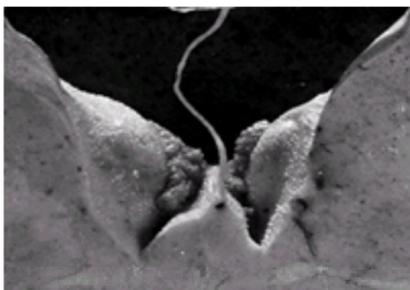

FIG. 27.3. Paretic neurosyphilis. Granular ependymitis of the floor of lateral ventricles. (From Merritt et al., 1946.)

Behavioral changes may suggest a psychosis, but the most common problem is dementia, with loss of memory, poor judgment, and emotional lability. In the final stages, dementia and quadriplegia are severe (general paresis of the insane). Seizures may occur.

If untreated, paretic neurosyphilis is fatal in 3 to 5 years. Penicillin is an effective treatment, but ultimately clinical results depend on the nature and extent of neuropathology when treatment is started. If inflammatory reaction is the only cause of the cerebral dysfunction, cure is likely. If spirochetal infection has already destroyed enough cerebral neurons, the infection may be arrested, but cerebral functions will not be restored.

Tabes Dorsalis

Tabes dorsalis, also called progressive locomotor ataxia, is manifested by lancinating or lightninglike pains, progressive ataxia, loss of tendon reflexes, loss of proprioception, dysfunction of sphincters, and impaired sexual function in men. The chief signs are loss of tendon reflexes at the knees and ankles, impaired vibratory and position sense in the legs, and abnormal pupils (Table 27.3).

Symptoms	%	Signs	%
Lancinating pains	75	Abnormal pupils	94
Ataxia	42	Argyll-Robertson	48
Bladder disturbance	33	Other abnormalities	64
Paresthesia	24	Reflex abnormalities	94
Gastric or visceral crises	18	Absent ankle jerks	81
Visual loss	16	Absent knee jerks	81
Rectal incontinence	14	Absent reflexes	11
Deafness	7	Romberg sign	55
Impotence	4	Impaired sensation	52
		Impaired vibratory sense	43
		Impaired vision	43
		Impaired touch and pain	13
		Optic atrophy	20
		Ocular palsy	10
		Charcot joints	7

From Merritt et al., 1946.

TABLE 27.3. SYMPTOMS AND SIGNS IN TABETIC NEUROSYPHILIS: ANALYSIS OF 150 CASES

In 94% of patients with tabes dorsalis, the pupils are irregular or unequal, or show impaired responses to light. In 48%, Argyll-Robertson pupils are present, with loss of the light reaction but with preservation of pupillary constriction in accommodation. Other findings include impaired superficial and deep sensation; weakness, wasting, and hypotonia of muscles; optic atrophy with visual loss; other cranial nerve palsies; and trophic changes, including Charcot joints or "mal perforant." Dysfunction of bowel, bladder, or genitals is also frequent.

Tabes dorsalis is seldom fatal. Ataxia or blindness may be incapacitating. Atonic bladder may lead to urinary tract infection and death. Progression may be arrested spontaneously or with treatment, but the lancinating pains and ataxia often continue.

Congenital Neurosyphilis

Congenital syphilis has been recognized since the 16th century. The spirochete is transmitted from the mother to the fetus between the fourth and seventh months of pregnancy. Mothers who have had syphilis for a longer time are less likely to give birth to an infected infant. The incidence of congenital neurosyphilis in North America has continued to decline with the improved detection and treatment of syphilis in adults, and it is now rare. The clinical types are similar to those in adults except that tabes dorsalis is uncommon. Additional features of congenital neurosyphilis are hydrocephalus and the Hutchinson triad (interstitial keratitis, deformed teeth, and hearing loss). The penicillin treatment schedule is similar to that in adults. Although the infection may be arrested, preexisting damage and neurologic signs may persist.

TREATMENT

Early Syphilis

The treatment of neurosyphilis begins with the treatment of early syphilis. The standard treatment has been a single intramuscular injection of 2.4 million U of penicillin G benzathine (Table 27.4 and Table 27.5). In early studies, the failure rate was about 4%.

Stage	Treatment
Primary, secondary, and early latent syphilis	Penicillin G benzathine, 2.4 million U i.m. For patients allergic to penicillin: doxycycline, 100 mg p.o. b.i.d. for 14 d; or tetracycline, 500 mg p.o. q.i.d. for 14 d
Late latent syphilis or duration unknown	Penicillin G benzathine, 7.2 million U i.m. given as 2.4 million U weekly for 3 wk For patients allergic to penicillin: doxycycline, 100 mg p.o. b.i.d. for 28 d; or tetracycline, 500 mg p.o. q.i.d. for 28 d
Tertiary disease other than neurosyphilis	As for late latent
Neurosyphilis	Penicillin G sodium, 12–24 million U daily i.v. (2–4 million U q4h) for 10–14 d; or penicillin G procaine, 2–4 million U i.m., plus probenecid, 500 mg p.o. q.i.d. for 10–14 d

Modified from Hook and Marra, 1992.

TABLE 27.4. RECOMMENDED TREATMENT FOR SYPHILIS

Immediate Diagnostic or Therapeutic Action	Further Investigation or Action
Primary syphilis Dark field or direct fluorescent test	VDRL titer for follow-up
Secondary syphilis VDRL titer	VDRL titer for follow-up
Suspected asymptomatic persons ^a VDRL titer	FTA-ABS if VDRL positive
Adequacy of treatment for early or late syphilis VDRL titer 3, 6, 12 mo after treatment	Retreat if high titer does not fall by 1/2 mo or if titer increases after retreat fail
Seropositive persons ^b CSF VDRL, CSF cell count	Treat for neurosyphilis if CSF VDRL positive or pleocytosis
Follow-up after treatment for asymptomatic neurosyphilis CSF cell count 6 wks, 3 mo, and 6 mo after treatment	CSF cell count at 12 mo, 24 mo if normal at 6 mo
Suspected syphilis ^c Treat as for early syphilis	VDRL titer 1, 3, and 6 mo after treatment

^aIncludes all pregnant women, proven contacts of people with infectious syphilis, and people in high-risk groups.
^bIncludes people with neurologic abnormalities, before treatment with neurosyphilis regimens, before 24 months after treatment failure.
^cIncludes women with recently untreated syphilis seropositivity late in pregnancy, contacts of neurologic with inadequately treated syphilis, proven contacts of those with infectious syphilis.
From Herl, 1986, with permission.

TABLE 27.5. RECOMMENDATIONS FOR USE OF DIAGNOSTIC TESTS FOR SYPHILIS

There is no prompt and reliable way to determine the adequacy of treatment. Instead, patients must return for repeat testing at 3, 6, and 12 months, or until serologic tests give negative results. Criteria for treatment failure (in the absence of reinfection) include the following: (1) persistent clinical signs of syphilis, (2) a fourfold rise in VDRL titer, and (3) a positive VDRL after 1 year in patients treated for primary syphilis or 2 years after treatment for secondary syphilis. The Centers for Disease Control and Prevention criterion is failure of the VDRL titer to drop by a factor of 2 within 6 to 12 months.

The occasional failure of this regimen has been documented when symptoms of neurosyphilis appeared after a few patients had received the standard dose of penicillin G benzathine. To avoid this problem, a fourth criterion for retreatment is being considered: a fourfold drop in VDRL titer at 3 months and an eightfold drop at 6 months. The general belief is that neurosyphilis can be prevented only if CSF is normal 2 years after treatment of early syphilis.

Neurosyphilis

Penicillin G benzathine does not provide therapeutic levels of the drug in CSF. Therefore, the recommended therapy for established neurosyphilis is intravenous administration of aqueous penicillin G, 12 to 24 million U daily for 10 to 14 days, or intramuscular aqueous penicillin G, 2.4 million U daily, with probenecid (Benemid), 2 g given orally each day. Probenecid enhances serum levels of penicillin by reducing renal excretion.

Penicillin may provoke allergic reactions of rash or anaphylaxis. The Jarisch-Herxheimer fever reaction may occur with any form of antisyphilitic treatment but seems to be less common in neurosyphilis. Effective alternatives for patients who are allergic to penicillin are doxycycline, 300 mg orally, given in divided doses daily for 30 days; or tetracycline, 500 mg four times daily for 14 days.

Gummas have responded to treatment with penicillin alone, penicillin plus steroids, and even steroids alone. If the clinical circumstances make that diagnosis likely, and if the clinical condition of the patient permits, a trial of conservative treatment is warranted. If the diagnosis is doubtful, or if the circumstances dictate more immediate attention, biopsy and excision may be appropriate.

For patients with both AIDS and any form of syphilis, some authorities advocate treatment with a regimen recommended for neurosyphilis.

After a course of therapy, quantitative blood serology is determined at 3-month intervals and usually shows a decline in titer if it had previously been elevated. Clinical neurologic examination should be performed regularly. The CSF is examined at 6 and 12 months. If not normal, CSF is reexamined in 2 years. After 3 years, if the patient has improved and is clinically stable and if the CSF and serologic tests are normal, neurologic and CSF examinations are discontinued.

Retreatment is recommended with high doses of intravenous penicillin G in the following situations: if the clinical neurologic findings progress without the discovery of another cause, especially if CSF pleocytosis persists; if the CSF cell count is not normal at 6 months; if the VDRL test in serum or CSF fails to show a decline or

shows a fourfold increase; or if the first course of treatment was suboptimal.

NEUROSYPHILIS AND AIDS

Neurosyphilis now probably occurs more often in HIV-positive persons than in those not HIV-infected. At least one-third of HIV-infected persons are coinfecting with *T. pallidum*. How HIV infection affects neurosyphilis is a matter of debate, but suspicions abound about concomitant HIV infection. For example, some authorities state that immunodeficiency reduces resistance to acquisition of syphilis and that the disease is more aggressive, with more frequent and more rapid progression to neurosyphilis and with increased severity, less response to therapy, and more frequent relapse. In one series, 20% of penicillin-treated patients had rising STS titers or new clinical signs. Some authors state that current treatment recommendations may be inadequate. Ophthalmic syphilis is more frequent. CSF cell counts and protein levels are higher, and the incidence of luetic meningitis has increased.

These views, however, are virtually all subjects of argument. The frequency of neurosyphilis in an HIV-positive population is probably less than 2%. In addition, *T. pallidum* is not more likely to invade the CNS. Postmortem examination showed no pathologic differences in neurosyphilis, regardless of whether or not the subjects were HIV-infected. There is no major difference in the clinical syndromes of neurosyphilis, and claims about more aggressive disease have been difficult to substantiate. Serologic responses to syphilis seem undiminished, and the infections respond to treatment as well. Penicillin therapy may be somewhat less effective in HIV-infected patients, but the clinical significance of this is uncertain. A reactive CSF VDRL test does not impair treatment responses.

The practical question is whether special syphilis treatment schedules are required for HIV-infected patients. A large trial of enhanced treatment of early syphilis included the addition of amoxicillin and probenecid to the conventional regimen; there was no decrease in the rate of treatment failure.

Therefore, there are no data to warrant enhanced treatment regimens for syphilis in HIV-infected people. The questions, however, reinforce the need for careful follow-up after treatment, so that retreatment can be given when needed. For patients who seem unlikely to comply, intravenous penicillin therapy (10 to 20 million U daily for 10 to 14 days) is an option. The declining incidence of syphilis and HIV infection may leave many of the questions unanswered because there may not be enough patients for large clinical trials.

CHAPTER 28. SPIROCHETE INFECTIONS: LEPTOSPIROSIS

JAMES R. MILLER

[Suggested Readings](#)

Leptospirosis is caused by a group of closely related spirochetes belonging to the genus *Leptospira*. The organisms that cause human disease are now thought to belong to a single species, *L. interrogans*, with subtypes such as *canicola*, *pomona*, and *icterohaemorrhagiae* recognized serologically. More than 170 serovariants are arranged in 18 serogroups.

Previously, specific serovariants were linked with particular clinical syndromes. Different serovariants, however, have been associated with the same or different clinical manifestations. Humans are incidental hosts for these spirochetes, which are enzootic in both wild and domestic animals, including cats, dogs, and cattle. Animals can become clinically sick, and asymptomatic carriers can excrete the spirochete in urine for months or years. Human infection comes from contact with infested animal tissue or urine or from exposure to contaminated groundwater, soil, or vegetation. *Leptospira* can survive for prolonged periods outside of hosts in appropriate environmental conditions. The spirochete is thought to enter humans through mucocutaneous abrasions; it is not known whether the organism can penetrate intact skin. Infection is not limited to specific human populations, but the incidence is probably higher in those who work with animal tissue, such as slaughterhouse employees, farmers, biologic laboratory workers, and persons preparing foods.

Symptoms usually appear abruptly 1 to 2 weeks after exposure, with chills, fever, myalgia, headache, and meningismus. Gastrointestinal symptoms include nausea, emesis, anorexia, and diarrhea. There may be cough and chest pain. Cardiac manifestations, including bradycardia and hypotension, can be severe. Conjunctival suffusion is typical but not constant. There may be pharyngeal injection, cutaneous hemorrhages, or maculopapular rash. Hepatosplenomegaly and lymphadenopathy may occur. In the acute first stage, there is septicemia, and the organism can be isolated from cerebrospinal fluid (CSF).

A second wave of symptoms may appear after the acute illness has apparently resolved. Original symptoms recur, sometimes with meningeal signs. Rarely, encephalitis, myelitis, optic neuritis, or peripheral neuritis develops. During the second phase of illness, immunoglobulin (Ig) M antibody to the *Leptospira* microorganisms and immune complexes can be found. Because the spirochete can no longer be isolated at this time, it is thought that the clinical disease of this phase is immune-mediated.

Leptospiral infection can be manifest clinically as aseptic meningitis. Although the agent can be recovered early in the syndrome, pleocytosis is not found until the second phase. Usually, cell counts are in the range of 10 to several hundred per cubic millimeter, but they can be higher. Neutrophils might be present early, but mononuclear cells predominate from the outset. Unlike most forms of viral meningitis, CSF protein can exceed 100 mg/dL in leptospirosis. Probably, all pathogenic serovariants (*canicola*, *icterohaemorrhagiae*, and *pomona*) can cause aseptic meningitis.

Other specific syndromes associated with leptospiral infection are pretibial (Fort Bragg) fever. Culture of the organism is possible if special facilities are available. Dark-field examination of blood, urine, or CSF is unreliable. Serologic studies usually confirm the clinical diagnosis, but the antibody is not detected until the second phase of the illness.

Various antibiotics can effectively treat leptospiral infection. They must be administered early in the illness. High-dose penicillin is most generally used; tetracycline is the alternative for those who are allergic to penicillin. Spontaneous recovery is the rule for younger patients without other illnesses. Mortality is greater than 50% after age 50 years, however, and is usually associated with severe liver disease and jaundice.

CHAPTER 29. SPIROCHETE INFECTIONS: LYME DISEASE

JAMES R. MILLER

[Epidemiology](#)
[Signs and Symptoms](#)
[Diagnosis](#)
[Treatment](#)
[Suggested Readings](#)

In 1975, a cluster of arthritis cases in children was recognized in Old Lyme, Connecticut. Many patients had had a migratory rash called erythema chronicum migrans (ECM), and some had neurologic or myocardial dysfunction. Affected adults also were seen. The syndrome was subsequently found to be caused by a previously unrecognized spirochete transmitted to humans by ixodid ticks. The spirochete has some characteristics of treponemes, but it is classified among the borreliae (*Borrelia burgdorferi*). In the northeastern United States, the vector, *Ixodes scapularis*, regularly infests deer and mice. Other animals are also hosts for the tick.

EPIDEMIOLOGY

The disease occurs throughout the United States in regions where ixodid ticks are found, although all ixodid populations do not appear to be equal in supporting the presence of the spirochete. The extent of human infection is unknown, but in the Lyme area antibodies are found in 4% of the population. In Europe, a *B. burgdorferi* strain is associated with a similar clinical disorder called *Bannwarth syndrome* or tick-borne *meningopolyneuritis* (Garin-Bujadoux, Bannwarth). Although the manifestations of the disease were described in Europe earlier in the century and were associated with ixodid ticks, the nature of the infection was determined only after the spirochete was identified in North America.

Genetic variation of the spirochete probably accounts for differences between the syndromes described in Europe and in the United States. In the narrow sense, *B. burgdorferi* refers to the American isolate, but broadly it represents a more inclusive term, referring to all the variants that cause similar syndromes. The worldwide distribution of the spirochetes and associated illnesses is still being defined, but symptomatic infection seems to occur throughout the world wherever appropriate ticks reside. *Neuroborreliosis* is sometimes used synonymously with Lyme disease. However, other borreliae that cause relapsing fever may also cause similar neurologic manifestations.

SIGNS AND SYMPTOMS

B. burgdorferi is most frequently transmitted to humans by the nymph stage of the tick, which is active in early summer, but transmission earlier or later can occur from contact with the adult arthropod. The organism can also be isolated from the tick larva, but it is difficult to recover from infected humans.

The course of infection in humans is variable. It has been divided into three stages, but overlaps in symptoms and in timing are common. Usually, a migrating erythematous ring (ECM) develops 3 to 32 days after exposure; the center of the rash is at the site of the tick bite. Smaller secondary rings often appear later, whose centers are less indurated than that of the primary lesion. At this stage, headache, myalgia, stiff neck, and even cranial nerve palsies (almost invariably the seventh nerve) can occur, but cerebrospinal fluid (CSF) is usually normal. The ECM usually resolves in 3 to 4 weeks, although transitory erythematous blotches and rings that do not migrate may occur later.

More prominent neurologic and cardiac manifestations are seen in the second stage, several weeks after the onset of ECM. Heart problems are usually confined to conduction defects, but there may be myopericarditis with left ventricular dysfunction. Meningeal symptoms and signs constitute the major features of the neurologic illness, with headache and stiff neck. Fever is not a regular feature. Radiculitis, multiple or isolated, is common and can cause severe root pain or focal weakness. Cranial nerves, usually the seventh, are frequently involved. Both sides of the face may become paralyzed simultaneously or sequentially. Polyneuritis or mononeuritis multiplex may also occur. Identifying the cause requires a sensitive index of suspicion in areas where the disease is endemic. Neurologic disease may also occur without previous ECM or recognized tick bite.

In original descriptions, *encephalopathic features* were noted, including ataxia, altered consciousness, and myelitis. Later, however, central nervous system (CNS) manifestations were less prominent, with decreased concentration, irritability, emotional lability, and memory and sleep disorders most usually noted. Because the disease is not fatal, the lesions that cause the neurologic syndromes have not been defined. *Immune-mediated processes*, including vasculitis, may be important.

The third stage of Lyme disease is characterized by chronic arthritis in patients with HLA-DR2 antigen. It usually appears several months after the original infection, but it can be present at the time of the subacute neurologic disease. The spirochete has not been isolated from joint fluid, and the arthritis could be an autoimmune disorder, although successful treatment of the arthritis with an antibiotic has been reported.

Although neurologic abnormalities have been mostly associated with the subacute second stage of the disease, a later chronic encephalomyelopathy has been associated with the infection. Often, white matter disease is evident on computed tomography (CT) or magnetic resonance imaging (MRI), usually in association with elevated Lyme disease spirochete antibody titers in blood or CSF. The syndrome is one of progressive long-tract dysfunction that may include optic nerve and sphincters. Cases characterized by only memory loss and cognitive dysfunction have also been reported. Response to antibiotic treatment has been variable. A syndrome of acral dysesthesias has been described in the late stage of Lyme disease. Electrophysiologic evidence reveals a neuropathic process, and the sensory symptoms respond to appropriate antibiotic therapy.

DIAGNOSIS

The combination of meningitis, radiculitis, and neuritis without fever occurs in virtually no other circumstance. If the appropriate history of tick exposure and ECM is obtained, the diagnosis is assured. Partial syndromes and absence of appropriate early findings, however, might require differentiation from a wide variety of illnesses ranging from herniated disc to other causes of acute aseptic or subacute meningitis. Brain MRI and CT scans are normal, and the electroencephalogram is usually normal or nonspecific. CSF pressure is normal. Abnormalities in the CSF formula are usually, but not always, present ([Table 29.1](#)). Oligoclonal bands are often present. *B. burgdorferi* has been isolated from the CSF, a rare technical feat that cannot be relied on for routine diagnosis. Demonstration of elevated levels of spirochete-specific immunoglobulin (Ig) M or IgG in the serum or of CSF by enzyme-linked immunosorbent assay or, less reliably, by immunofluorescent antibody test constitutes the basis of diagnosis in clinically appropriate circumstances. Specific confirmation of elevated titers is often sought by Western blot reaction to spirochetal proteins. The procedure is complicated by frequent cross-reactions with other proteins, and strict criteria of interpretation are required for the test to be useful.

Test	CSF
Opening pressure ^a	Normal
Total white cells/mm ³	166 (15–700) ^b
Lymphocytes (%)	93 (40–100)
Glucose (mg/dL) ^c	49 (33–61)
Protein (mg/dL)	79 (8–400)
IgG/albumin ratio (n=20)	0.18 (0.5–0.44)
Oligoclonal bands (n=4)	Present
Myelin basic protein (n=5)	Absent

TABLE 29.1. CSF ANALYSIS IN LYME DISEASE ENCEPHALOMYELITIS

The diagnosis of Lyme disease, particularly chronic encephalomyelopathy, is complicated by vagaries of the immune response and the indefinite clinical picture. Rapid treatment of Lyme disease in the early stages, or perhaps even intercurrent use of antibiotics for other purposes, may result in the absence of agent-specific antibody response when the more chronic syndromes become apparent. In addition, antibody carriers in endemic areas may be asymptomatic, making the presence of antibodies inconclusive in questionable cases. Brain single-photon emission CT has been suggested as a method for determining abnormality when other imaging procedures are normal. The specificity of the abnormalities for Lyme disease as opposed to other encephalopathies, however, is not yet determined. The ambiguities in diagnosis of chronic encephalomyelopathies have led to a generous use of prolonged antibiotic treatment in doubtful circumstances, sometimes when other neurologic problems, such as multiple sclerosis, are clearly the cause. Polymerase chain reaction technology and sensitive immunoassays have been applied to the detection of *B. burgdorferi* deoxyribonucleic acid and antigens in the CSF, but their usefulness is still undetermined.

TREATMENT

Doxycycline, amoxicillin, and clarithromycin (Biaxin) have become the common medications for treatment of Lyme disease during the early stage characterized by ECM. Tetracycline or azithromycin (Zithromax) are also still used. These agents usually prevent the development of subsequent stages. Intravenously administered third-generation cephalosporins, usually ceftriaxone sodium (Rocephin) or cefuroxime axetil (Ceftin), are now generally employed for treatment of neurologic symptoms. Before antibiotic therapy, the second-stage neurologic syndrome lasted for a mean of 30 weeks, although the intensity fluctuated. Intravenous antibiotics usually cause acute symptoms to resolve as the agents are being given. Motor signs last a mean of 7 to 8 weeks, irrespective of the use of antibiotics.

It is now recognized that even with mild CNS involvement, a prolonged period of subtle to moderate memory, emotional, and cognitive problems may follow successful treatment. In the best documented late encephalomyelopathy cases, several months were required after treatment before clinical improvement was noted. The proper length of treatment is uncertain. For most straightforward cases, 2 to 3 weeks seems sufficient. As more chronic and less well documented cases have been treated, the tendency is to treat longer, even up to several months. The efficacy of prolonged treatment has not been established. Antibiotic doses appropriate for ECM therapy are sufficient to treat isolated nerve palsies associated with elevated spirochete antibody levels.

The U.S. Food and Drug Administration has approved the use of a vaccine constituted against the spirochete's outer-surface protein A (OspA). A second vaccine against the same antigen is likely to be approved. Both vaccines require three inoculations for full efficacy and protection, and are about 80% effective after the full series. The length of protection following a single series is not yet known. The vaccines are not yet approved for children younger than 12 years. Recommendations are for those who live in areas where the ticks are endemic and for those who are frequently outdoors in these areas.

CHAPTER 30. PARASITIC INFECTIONS

BURK JUBELT AND JAMES R. MILLER

[Helminthic Infection](#)
[Protozoan Infection](#)
[Suggested Readings](#)

Disease caused by parasites is uncommon in developed countries. In tropical and less-developed areas, however, parasitic infections exact a heavy toll on society. Poverty and poor living conditions play a significant role in the pathogenesis of these infections, but an appropriate climate for vectors to facilitate transmission is also necessary. The combination of increased international travel to and immigration from endemic areas has increased the likelihood of encountering tropical parasitic infections in the United States. Indigenous parasites are being encountered more frequently because of long-term survival of immunosuppressed patients who have increased susceptibility to infection.

Parasitic infections can be divided into two categories: those caused by worms (helminths) and those caused by protozoa.

HELMINTHIC INFECTION

Helminths are large complex organisms that frequently elicit systemic allergic responses (eosinophilia) and more often cause focal, rather than diffuse, involvement of the nervous system. Helminths are divided into tapeworms (cestodes), flukes (trematodes), and roundworms (nematodes) ([Table 30.1](#)).

Disease/Parasite	Geographic Location
Cestodes (tapeworms)	
Cysticercosis	Asia, Africa, Central and South America, Eastern Europe
<i>Taenia solium</i>	Worldwide
Echinococcosis (hydatid cyst disease)	
Trematodes (flukes)	
Schistosomiasis	Far East
<i>S. japonicum</i>	South America, Caribbean, Africa, and Middle East
<i>S. mansoni</i>	Africa, Middle East
<i>S. haematobium</i>	Asia, Central Africa, Central and South America
Paragonimiasis	
Nematodes (roundworms)	
Trichinosis	Worldwide
Eosinophilic meningitis	Southeast Asia, Pacific Islands, Hawaii, Cuba, and Africa
<i>Angiostrongylus cantonensis</i>	
<i>Gnathostoma spinigerum</i>	
Toxocarosis	Worldwide
(visceral larva migrans)	
Strongyloidiasis	Tropical and subtropical regions, including United States

TABLE 30.1. COMMON HELMINTHIC INFECTIONS OF THE NERVOUS SYSTEM

Cysticercosis

Cysticercosis is the result of encystment of the larvae of *Taenia solium*, the pork tapeworm, in the tissues. The infestation is acquired by ingestion of the ova usually by fecal contamination of food or less often by autoinfection via anal–oral transfer or reverse peristalsis of proglottids into the stomach. The larvae are not acquired by eating infected pork, and cysticercosis regularly occurs in vegetarians in endemic areas. Ingestion of infected pork results in the adult tapeworm infection.

Incidence

Central nervous system (CNS) involvement occurs in 50% to 70% of all cases. Virtually all symptomatic patients have CNS involvement. It is the most common parasitic infection of the CNS. Cerebral cysticercosis is common in Mexico, Central and South America, Southeast Asia, China, and India. The disease has again become relatively common in the United States because of immigration from Mexico. The disease may occur in other areas where a reservoir of infected pigs exists. In Mexico, cerebral cysticercosis is found in 2% to 4% of the population in unselected autopsy studies.

Pathology

Typical cysts measure 5 to 10 mm and may be discrete and encapsulated or delicate, thin-walled, and multicystic. The miliary form with hundreds of cysticerci is most common in children. Meningeal cysts cause a chronic cerebrospinal fluid (CSF) pleocytosis. Live encysted larvae in the parenchyma cause little inflammation. Inflammation occurs when the larvae die, usually years after ingestion, and often correlates with the onset of symptoms.

Symptoms and Signs

Clinical manifestations can be divided into four basic types, depending on anatomic site: parenchymal, subarachnoid (or meningitic), intraventricular, and spinal. The most common presenting manifestations are seizures, increased intracranial pressure with headaches and papilledema, and meningitis.

In the parenchymal form, symptoms are related to the site of encystment. Cortical cysts frequently give rise to focal or generalized seizures. Other focal deficits may appear suddenly or may be more chronic. Signs include hemiparesis, sensory loss, homonymous hemianopia, aphasia, or ataxia from cerebellar cysts. Stroke, which occurs secondary to vessel involvement, and dementia are occasionally seen. Rarely, an acute diffuse encephalitis, with confusion to coma, is seen at the time of the initial infection.

The subarachnoid form may be the result of the rupture or death of an arachnoidal cyst or its transformation into the racemose form of the organism, which can enlarge within the basal cisterns and cause obstructive hydrocephalus. Symptoms of meningeal involvement vary from mild headache to a syndrome of chronic meningitis with meningism and communicating hydrocephalus. Spinal involvement may occur and may evolve into arachnoiditis and complete spinal subarachnoid block.

Cysts in the third or fourth ventricle (intraventricular form) obstruct the flow of CSF and can result in obstructive hydrocephalus. The cyst may move within the ventricular cavity and produce a “ball-valve” effect, resulting in intermittent symptoms. Sudden death may occur in these patients, occasionally without prior symptoms. This form frequently occurs in conjunction with the subarachnoid form.

The spinal form is rare. Extramedullary intradural lesions, which are usually cervical, and intramedullary lesions, which are usually thoracic, may be present.

Laboratory Data and Diagnosis

The diagnosis of cysticercosis should be considered in all patients who have ever resided in endemic areas and who have epilepsy, meningitis, or increased intracranial pressure. Computed tomography (CT) and magnetic resonance imaging (MRI) are useful in evaluating such patients. Hydrocephalus may be observed and the exact site of obstruction determined. Intravenous contrast material may demonstrate intraventricular cysts. Parenchymal cysts may calcify, revealing single or multiple punctate calcifications on CT. Viable cysts appear as small lucent areas that may be enhanced either diffusely or in a ring pattern after the infusion of intravenous contrast material ([Fig. 30.1](#)). CSF examination may be normal or may reveal a moderate pleocytosis and elevated pressure. In more severe meningitis, the CSF may contain several hundred to several thousand white blood cells (usually mononuclear), elevated protein content, and low glucose, presenting a clinical picture similar to that for fungal or tuberculous meningitis. Eosinophilic meningitis is occasionally seen but is uncommon. The presence of eosinophilia in the blood

suggests another parasitic infestation and does not occur in pure neurocysticercosis. CSF or serum antibody (complement fixation, ELISA, Western blot) are usually positive.

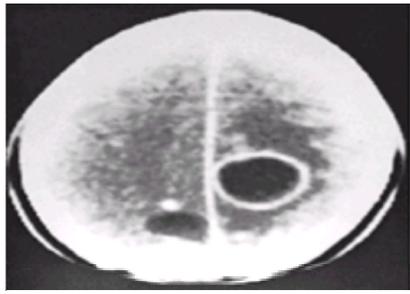

FIG. 30.1. Cerebral cysticercosis: computed tomography. Patient with partial seizures and normal examination. A large lucent lesion with rim enhancement is seen on the left. A nonenhancing lucency with small calcification appears in the right parietal region. Other small lesions are seen bilaterally. (Courtesy of Drs. Verity Grinnell and Mark A. Goldberg.)

Treatment

Ventricular shunting is usually adequate for treatment of hydrocephalic forms of this disorder. Seizures can be controlled with anticonvulsants. Intractable seizures may develop, and surgical removal of cysts may be beneficial. Corticosteroids have been used to relieve the meningitic symptoms, but their value has not been established. Praziquantel, effective in stopping the progression of the parenchymal form of cysticercosis, was the first drug used successfully against the cysts. It is less effective for the chronic meningitic form with arachnoiditis. Albendazole has greater anticysticercal activity and is now the drug of choice. Concomitant use of corticosteroids may be required to prevent severe inflammatory reactions and edema in response to the dying cysticerci.

Echinococcosis (Hydatid Cysts)

Echinococcosis is a tissue infection of humans caused by the larvae of *Echinococcus granulosus*, a tapeworm parasite of the dog family. There is an intermediate phase of development with hydatid cyst formation in other mammals. Sheep and cattle are usually the intermediate hosts, but humans may be infected, especially by ova shed in dog feces. The disease is most common in countries where herd dogs assist with sheep and cattle raising. It is rare in the United States. Several other *Echinococcus* species rarely infect the human CNS.

The cysts are most commonly found in the liver and the lungs. If the embryos pass the pulmonary barrier, cyst formation may occur in any organ. The brain is involved in about 2% of the cases, and neurologic symptoms may develop in patients with cysts in the skull or spine.

Cerebral cysts are usually single. They are most common in the cerebral hemispheres but may develop in the ventricles or cerebellum. The infestation may occur at any age but is most common in children from rural areas.

The signs and symptoms that develop with enlarging cysts in the brain are similar to those of tumor in the affected region. Seizures and increased intracranial pressure may also occur. Involvement of the spine may result in spinal cord compression. The diagnosis of hydatid cyst as the cause of cerebral symptoms is rarely made before operation. CT and MRI should be used to localize the lesions, which are usually single, nonenhancing, and of CSF density. Needle biopsy usually is precluded, because rupture of a cyst results in allergic manifestations, including anaphylaxis. In spinal disease, vertebral collapse is common and is evident on x-rays. Eosinophilia is uncommon except after cyst rupture. Liver enzymes are usually normal. Serologic tests are positive in 60% to 90% of infected individuals.

Treatment is complete surgical removal without puncturing the cyst. Drug treatment with albendazole may decrease the size of cysts and prevent allergic reactions and secondary hydatidosis at the time of surgery.

Schistosomiasis (Bilharziasis)

Involvement of the nervous system by the ova of trematodes is rare. In most reported cases, the lesions were associated with infection with *Schistosoma japonicum*, but isolated cases of *S. haematobium* and *S. mansoni* have also been recorded. *S. japonicum* has a predilection for the cerebral hemispheres; *S. haematobium* and *S. mansoni* more frequently affect the spinal cord. These predilections appear to relate to the location of the adult worms from where ova are released. *S. japonicum* resides in superior mesenteric venules, but the occurrence of ectopic worms in cerebral venules may explain in part the high incidence of cerebral involvement. *S. mansoni* primarily resides in the inferior mesenteric venules, whereas *S. haematobium* is found in the vesical plexus.

Pathology

The presence of the ova in the nervous system causes an inflammatory exudate containing eosinophils and giant cells (granulomas), necrosis of the parenchyma, and deposition of calcium.

Epidemiology

Schistosomiasis is one of the most important worldwide parasitic diseases, occurring in over 200 million people. *S. japonicum* occurs mainly in Asia and in the Pacific tropics. *S. mansoni* is prevalent in the Caribbean, South America, Africa, and the Middle East. *S. haematobium* occurs in Africa and the Middle East. Symptoms may occur within a few months of exposure or may be delayed for 1 to 2 years. Relapses may occur several or many years after the original infection. The CNS is involved in 3% to 5% of the patients with *S. japonicum* but in fewer patients with other species.

Clinical Manifestations

Schistosomiasis occurs in three phases. The first, or cercarial dermatitis, is an acute reaction to the penetration of the skin by cercariae. The second is a serum sickness reaction, Katayama fever, that occurs 6 to 8 weeks after exposure and manifests as fever, urticaria, abdominal pain, diarrhea, and muscle pain. The third stage is a chronic infection of most internal organs (liver, spleen, bladder, heart, lungs). Cerebral schistosomiasis may be acute during Katayama fever or chronic with the third phase. Acute cases usually present as a diffuse fulminating meningoencephalitis with fever, headache, confusion, lethargy, and coma. Focal or generalized seizures, hemiplegia, and other focal neurologic signs are common. The chronic cerebral form usually simulates the clinical picture of a tumor with localizing signs and increased intracranial pressure with papilledema. Granulomatous masses in the spinal cord almost always present acutely with signs and symptoms of an incomplete transverse lesion, with or without spinal subarachnoid block, depending on the size of the lesion. The conus is the most common site of spinal cord involvement. Granulomatous root involvement may also occur.

Laboratory Data

There is leukocytosis with an increase in eosinophils in the blood, although this may not be the case with the chronic cerebral form. The CSF pressure may be increased with large intracerebral lesions and partial or incomplete subarachnoid block with spinal lesions. A slight or moderate pleocytosis in the CSF (sometimes with eosinophils) and an increased protein content may occur. Cerebral lesions may be seen with CT or MRI. Spinal cord lesions may be demonstrated by myelography, CT, or MRI (Fig. 30.2).

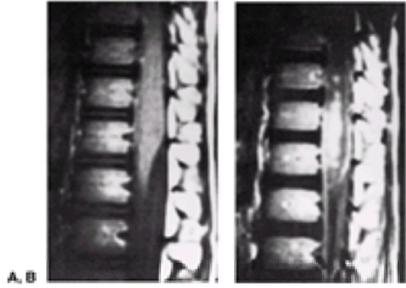

FIG. 30.2. Spinal cord schistosomiasis: sagittal T1-weighted magnetic resonance images. **A:** Without contrast demonstrates markedly enlarged conus medullaris. **B:** With contrast demonstrates prominent regions of enhancement within the enlarged conus. [From Selwa et al. (1991).]

Diagnosis

The diagnosis is established from the history of gastrointestinal upset, eosinophilia in the blood, and the presence of ova in the stool or urine. Serologic tests and biopsy of the rectal mucosa are also of value in the establishment of the diagnosis.

Treatment

The broad-spectrum drug praziquantel is the drug of choice. It is effective against all three human schistosomes. Oral steroids may decrease swelling. Anticonvulsive drugs should be given to control seizures. Surgical excision of the large granulomatous lesions may be required. Steroids and decompressive laminectomy may be needed when subarachnoid block is present.

Paragonimiasis

Paragonimiasis is the disease caused by the lung flukes *Paragonimus westermani* and *P. mexicanus*. Other *Paragonimus* species may rarely infect humans. These trematodes commonly infect humans in Africa, Southeast Asia, South Pacific areas, India, and Central and South America. Infection occurs by eating uncooked or poorly cooked freshwater crustaceans. Immature flukes exist in the intestines and spread through the body, occasionally reaching the brain and spinal cord. Pulmonary and intestinal symptoms are the most common. Pulmonary involvement includes chronic cough, hemoptysis, and cavitory lesions on chest radiographs, thus simulating tuberculosis.

CNS involvement occurs in 10% to 15% of affected patients. Symptoms and signs of cerebral involvement include fever, headache, meningoencephalitis, focal and generalized seizures, dementia, hemiparesis, visual disturbances, and other focal manifestations. Various syndromes have been recognized: acute meningitis, chronic meningitis, acute purulent meningoencephalitis, infarction, epilepsy, subacute progressive encephalopathy, chronic granulomatous disease (tumorous form), and late inactive forms (chronic brain syndrome). The CSF may be under increased pressure. The pleocytosis is primarily polymorphonuclear in acute forms and lymphocytic in more chronic forms. Eosinophils are occasionally present, and many red blood cells are occasionally seen in the acute cases. The protein content and gamma globulins are usually increased. The glucose content may be decreased. Diagnosis is most often made by detecting ova in the sputum and stool. Peripheral anemia, eosinophilia, leukocytosis, and elevated erythrocyte sedimentation rate and gamma globulins may occur. Serologic and skin tests are available. Positive CSF antibody tests are diagnostic but not very sensitive. CT may also be of assistance in diagnosis, revealing ventricular dilatation and intracranial calcifications, including the characteristic "soap bubble" calcifications. During the early progressive course, mortality may reach 5% to 10%. The later chronic granulomatous state tends to be benign. Therapy includes praziquantel or bithionol for the acute to subacute meningoencephalitis and surgical treatment for the chronic tumorous form.

Trichinosis (Trichinellosis)

Trichinosis is an acute infection caused by the roundworm *Trichinella spiralis*. Infection is acquired by eating larvae (in cysts) in raw or undercooked pork. Bear and walrus meat have also been incriminated. The CNS is involved in 10% to 17% of cases.

Pathology

The pathologic changes in the nervous system include the presence of filiform larvae in the cerebral capillaries and in the parenchyma, perivascular inflammation, petechial hemorrhages, and granulomatous nodules.

Symptoms and Signs

Trichinosis manifests as a systemic infection due to larval migration (larviposition) with fever, headache, muscle pain and tenderness (muscle invasion), periorbital edema, subconjunctival hemorrhages, and myocardial involvement. Gastrointestinal symptoms are less frequent, occurring in about 25% of symptomatic cases. Neurologic involvement occurs in 10% to 25% of symptomatic infections and develops any time within the first few weeks of the infection. There may be a severe diffuse encephalitis with confusion, delirium, coma, seizures, and evidence of focal damage to the cerebrum, brainstem, or cerebellum. Edema of the optic nerve, meningeal signs, spinal cord syndromes, and neuropathies may also occur.

Laboratory Data

The most important laboratory findings are leukocytosis and eosinophilia in the blood. Muscle enzymes may be increased. The CSF is abnormal in about one-third of cases. There may be a slight lymphocyte pleocytosis, but eosinophilia is rare. The protein content and pressure are often elevated. The parasites are found in the CSF of approximately 30% of patients. CTs may reveal single or multiple small hypodensities in the white matter or cortex in about three-fourths of cases, with about half of these lesions enhancing with contrast.

Diagnosis

The diagnosis is usually not difficult when neurologic symptoms appear in a group of individuals who have eaten infected pork and show the other manifestations of the disease (gastrointestinal symptoms, tenderness of the muscles, and edema of the eyelids). Difficulty is encountered in isolated cases when infection results from ingestion of meat other than pork or where the other manifestations of the infection are lacking. Trichinosis should be considered an etiologic factor in all patients with encephalitis of obscure nature. Repeated examination of the blood for eosinophilia and elevated muscle enzymes, biopsy of the muscles, and serologic tests should establish the diagnosis.

Prognosis

Recovery within a few days or weeks is the rule except when there is profound coma or evidence of severe damage to the cerebrum. For those with CNS involvement, mortality is 10% to 20%. Recovery is usually accompanied by complete or almost complete remission of the neurologic signs. Recurrent convulsive seizures have been reported as a late sequel.

Treatment

Thiabendazole is recommended to kill intestinal worms. Mebendazole is used to treat tissue larvae. Corticosteroids are given to reduce inflammation and cerebral

edema.

Eosinophilic Meningitis

The human nervous system may be invaded by the nematode rat lungworm, *Angiostrongylus cantonensis*, which uses a molluscan intermediate host and invades the domestic rat and other rodents in the course of its life cycle. Infection in humans (accidental hosts) is usually due to the ingestion of raw snails, shrimp, crabs, and fish, which are the intermediate hosts. Cases have been reported from Hawaii, the Philippines, Pacific Islands, Southeast Asia, Cuba, and Africa.

Involvement of the human nervous system is usually characterized by an acute meningitis (headache 90%, nuchal rigidity 60%, fever 50%), but less frequently there may be encephalitis, encephalomyelitis, radiculomyeloencephalitis, or involvement of cranial nerves (especially VI and VII). Onset occurs 3 to 35 days after the ingestion of the raw intermediate host. Severe dysesthetic pains, probably from posterior root inflammation, occur in about 50% of the patients. The infection is most common in children. Nervous system lesions are due to destruction of tissue by the parasite and to necrosis and aneurysmal dilatation of cerebral vessels, resulting in small or large hemorrhages. A CSF pleocytosis of 100 to 1000 cells/mm³ with many eosinophils is characteristic. A peripheral blood eosinophilia is almost always seen. CT is usually normal. Serologic tests are available. Usually, the disease is self-limited. In severe cases, death, which is rare, may be the result of small or large hemorrhagic lesions in the brain. There is no specific therapy.

Not all cases of eosinophilic meningitis are due to *A. cantonensis* infestation; other parasitic infections (cysticercosis, schistosomiasis, paragonimiasis), coccidioidomycosis, foreign bodies, drug allergies, and neoplasms may also cause this syndrome but less frequently. Another nematode of the Far East, *Gnathostoma spinigerum*, usually causes eosinophilic meningitis when it invades the CNS; such invasion occurs much less frequently with *G. spinigerum* than with *A. cantonensis*. It has also caused the clinical syndromes of radiculomyelitis, encephalitis, and subarachnoid and intracranial hemorrhage. When the CNS is involved, the symptoms are more severe and the mortality is higher with *G. spinigerum*, probably because of its larger size, than with *A. cantonensis* infection. Also, with *G. spinigerum*, CT is usually abnormal because parenchymal disease (brain and spinal cord) is more common.

Other Helminths

In toxocariasis, visceral larva migrans is a syndrome of pulmonary symptoms, hepatomegaly, and chronic eosinophilia caused by the larvae of the dog and cat ascarids (roundworms) *Toxocara canis* and *T. cati*. Eggs from the animals' feces may be ingested, especially by children playing with infected dogs or contaminated soil. Although visceral larva migrans is uncommon and nervous system involvement is rare, the disease is always a potential threat due to the ubiquitous infections of domestic animals. Neurologic signs are most often manifest by focal deficits, especially hemiparesis. Encephalopathy and seizures also have occurred. Eosinophils are infrequently seen in the CSF but are common in the periphery. Ocular involvement is more common than CNS disease. Serology is helpful for diagnosis, and hypergammaglobulinemia is common. Larvae may be identified in the sputum or in tissue granulomas from biopsy. Diethylcarbamazine is the drug of choice. Thiabendazole and mebendazole are alternative agents. An association of toxocariasis with pica and lead encephalopathy has been noted. Another ascarid, *Ascaris lumbricoides*, has been reported to cause a similar neurologic syndrome.

Strongyloidiasis is an intestinal infection of humans caused by the nematode *Strongyloides stercoralis*. This infection occurs in tropical and subtropical regions throughout the world but also occurs in most areas of the United States. In the usual infection, the CNS is spared. Disseminated strongyloidiasis (hyperinfection syndrome), however, is not an infrequent complication in the immunosuppressed or immunodeficient host. CNS involvement occurs as part of this disseminated infection. Neurologic signs include meningitis, altered mental states (encephalopathy to coma), seizures, and focal deficits from mass lesions or infarction. CSF abnormalities are nonspecific, and eosinophilia is infrequent. Diagnosis is usually made by finding the larvae in stool, sputum, or duodenal aspirates. Peripheral eosinophilia is not always present. Another clue to the diagnosis is the occurrence in the immunocompromised patient of an unexplained gram-negative bacteremia and meningitis, which is a frequent accompaniment of disseminated strongyloidiasis. Thiabendazole and ivermectin are the drugs of choice.

PROTOZOAN INFECTION

Protozoa are small (microbial size) single-cell organisms that more frequently cause diffuse encephalitic, as opposed to focal, involvement of the nervous system. Protozoa do not elicit allergic reactions or cause eosinophilia.

Toxoplasmosis

Toxoplasmosis is the infection of humans by the protozoan organism *Toxoplasma gondii*. The infection, which has a predilection for the CNS and the eye, may be congenital with encephalitis and chorioretinitis; may cause meningoencephalitis during acquired primary infection in the immunocompetent host; and may cause mass lesions, encephalitis, and chorioretinitis in the immunocompromised host. Toxoplasmosis is especially prevalent in those with acquired immunodeficiency syndrome (AIDS) (see [Chapter 24](#)).

Etiology and Pathology

The toxoplasma are minute (about 2 × 3 μm), oval, pyriform, rounded, or elongated protoplasmic masses with a central nucleus. The important animal host for this organism is the cat. Infection is acquired by ingestion of oocysts from cat feces or contaminated soil. Infection may also occur by eating unwashed vegetables or undercooked meat. The organisms invade the walls of blood vessels in the nervous system and produce an inflammatory reaction. Miliary granulomas are formed. They may become calcified or undergo necrosis. The granulomatous lesions are scattered throughout the CNS and may be found in the meninges and ependyma. Hydrocephalus may develop from occlusion of the aqueduct of Sylvius by the resulting ependymitis. The microorganisms are present in the epithelioid cells of the granulomas, endothelial cells of blood vessels, and nerve cells. Lesions in the retina are common; occasionally, they are also present in the lungs, kidneys, liver, spleen, or skin.

Clinical Manifestations

In the congenital form, the symptoms are usually evident in the first few days of life. Rarely, congenital infections may not manifest for several years. The common manifestations are inanition, microcephaly, seizures, mental retardation, spasticity, opisthotonos, chorioretinitis, microphthalmus, or other congenital defects in development of the eye. Optic atrophy is common, and there may be an internal hydrocephalus. Depending on the extent of systemic disease, the liver and spleen may be enlarged with elevated bilirubin; fever, rash, and pneumonitis may also be present. The presence of calcified nodules in the brain can be demonstrated by CT or radiographs of the skull. Symptoms in the infantile form are similar to those of the congenital form but may not make their appearance until the third or fifth year of life. Cerebral calcifications are not found in postnatally acquired infections.

Acquired toxoplasmosis is most often asymptomatic in the normal host. An infectious mononucleosis-like picture may be seen with lymphadenopathy and fever. Although atypical lymphocytes may be present in the peripheral blood, serologic tests for Epstein-Barr virus are negative. Rarely, meningoencephalitis with headache, confusion, delirium, drowsiness, and coma with seizures can be seen. Signs of meningeal irritation are uncommon.

Severe infection is more likely to occur in immunocompromised patients, and some may be due to reactivation rather than to newly acquired infection. Extraneural manifestations may include pneumonitis, myocarditis, myositis, and choreoretinitis. Neurologic involvement may take one of several forms: subacute to chronic encephalopathic picture with confusion, delirium, obtundation, and coma, occasionally accompanied by seizures; acute meningoencephalitis with headache, nuchal rigidity, and focal or generalized seizures, leading to status epilepticus and coma; and focal signs due to single or multiple mass lesions (toxoplasmic abscess), probably the most common and tends to be chronic. A combination of these three types of neurologic involvement is often seen.

Toxoplasmosis as a complication of neoplastic disease is relatively infrequent. Toxoplasmosis, however, is one of the most frequent CNS opportunistic infection of AIDS patients, accounting for about one-third of all CNS complications.

Laboratory Data

A moderate or severe anemia and a mild leukocytosis or leukopenia may be present. The CSF may be under increased pressure. The protein content is generally increased, and there is an inconstant pleocytosis. Cell counts as high as several thousand per cubic millimeter, mostly lymphocytes, have been recorded. The CSF

glucose is normal or mildly reduced. CT may reveal calcifications in congenital infections. Low-density focal lesions may be seen. With contrast, these lesions usually show ring enhancement similar to a brain abscess or, less frequently, diffuse or no enhancement. Often, the lesions are multiple. MRI is more sensitive for demonstrating these lesions ([Fig. 30.3](#)).

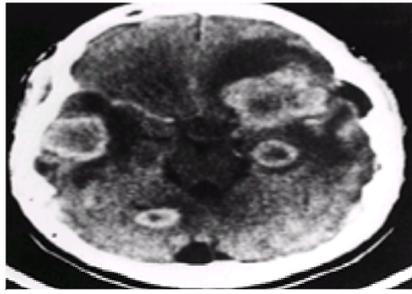

FIG. 30.3. Cerebral toxoplasmosis. Enhanced axial computed tomography demonstrates multiple, bilateral, ring-enhancing hypodense lesions of both temporal, right occipital and left frontal lobes with surrounding edema. (From Farrar WE, Wood MJ, Innes JA, Tubbs H. *Infectious diseases: text and color atlas*, 2nd ed. London: Gower Medical Publishers, 1992:3.30.)

Diagnosis

The diagnosis of congenital toxoplasmosis is usually considered in the newborn with choreoretinitis, microcephaly, seizures, mental retardation, cerebral calcifications, and evidence of systemic infection. The diagnosis is more difficult to make in older children and adults with either acquired disease or reactivation of a latent infection. *Toxoplasma* can occasionally be demonstrated in CSF sediment with Wright or Giemsa stain. The organism rarely can be cultivated from CSF sediment by inoculation of laboratory mice. Tissue culture and polymerase chain reaction techniques are still under development but may be available in some locales. Although a definite diagnosis can be made only by isolation of the organism from biopsy of brain or other tissues, a presumptive diagnosis can be made by using readily available serologic tests. Serologic tests include the Sabin-Feldman dye, indirect fluorescent antibody, complement fixation, agglutination, indirect hemagglutination, and ELISA tests. Demonstration of IgM antibodies by ELISA or indirect fluorescent antibody is particularly helpful for diagnosis of a congenital or an acute acquired infection.

In AIDS patients and in most immunocompromised patients, serum IgG antibody is usually positive, although a fourfold rise is infrequent. Serum IgM antibody is not usually detected. The presence of CSF antibodies may be a sensitive indicator of CNS infection.

Course, Prognosis, and Treatment

Prognosis is poor in the congenital form; more than 50% of affected infants die within a few weeks after birth. Mental and neurologic defects are present in the infants who survive. The mortality rate is also high in the infantile form of encephalitis. Most acquired infections in the immunocompetent patient are self-limited and do not require treatment. The severe, acquired, or reactivated infections, which occur more commonly in immunocompromised patients, frequently result in death. These severe infections can at times be treated successfully with pyrimethamine and sulfadiazine. In AIDS patients, if a tissue diagnosis cannot be made but serum IgG titers are positive and the characteristic neuroradiologic abnormalities are present, empiric therapy should be instituted. Indefinite suppression therapy is required for AIDS patients.

Cerebral Malaria

Malaria is the most common human parasitic disease, with 300 million to 500 million infected individuals in the world and about 2 million deaths each year. This disease is endemic in tropical and subtropical areas of Africa, Asia, and Central and South America. The disease can be seen almost anywhere, however, as a result of international travel. Malaria is transmitted by mosquitos.

Involvement of the nervous system occurs in about 2% of affected patients and is most common in infections of the malignant tertian form, almost always caused by *Plasmodium falciparum*.

Pathology and Pathogenesis

The neurologic symptoms are due to congestion or occlusion of capillaries and venules with pigment-laden parasitized erythrocytes and to the presence of multiple petechial hemorrhages. Apparently, parasitized erythrocytes adhere to vascular endothelial cells, thereby obstructing blood flow and causing anoxia. Lymphocytic and mononuclear perivascular inflammation and a microglial cell response may be seen, at times resulting in cerebral edema. Thrombotic occlusion of vessels and large intracranial hemorrhages are rare. It is probable that the pathologic changes in the nervous system are reversible.

Symptoms and Signs

The symptoms and signs are primarily those of an acute diffuse encephalopathy. Spinal cord lesions and a polyneuritis of the Guillain-Barré type have rarely been seen. The neurologic symptoms usually appear in the second or third week of the illness but may be the initial manifestation. The onset of cerebral symptoms has no relationship to the height of the fever. Headache, photophobia, vertigo, convulsions, confusion, delirium, and coma are the most common symptoms. There may be neck stiffness. Focal signs, such as transient hemiparesis, aphasia, hemianopia, and cerebellar ataxia, are uncommon. Myoclonus, chorea, and intention tremors have been observed. Cranial nerve palsies and papilledema are rarely seen, although retinal hemorrhages are common. Psychic manifestations, such as delirium, disorientation, amnesia, or combativeness, are present in a large percentage of the patients. In severe malaria, pulmonary edema, renal failure, and gastrointestinal symptoms occur.

Laboratory Data

Laboratory findings include anemia and the presence in the red blood cells of many parasites. In most cases, the CSF is entirely normal. Elevated pressure, slight xanthochromia, a small or moderate number of lymphocytes, and a moderately increased protein content may be seen. CSF sugar content is normal.

Diagnosis

Cerebral malaria is diagnosed from the appearance of cerebral symptoms and the findings of the organisms of *P. falciparum* by microscopic examination of blood smears. ELISA kits for serologic diagnosis are available. Delirium, convulsions, or coma, probably because of high fever, may occur as symptoms of general infection in patients with *P. vivax* in the absence of cerebral involvement. The symptoms in these cases are transient and respond readily to antimalarial therapy.

Prognosis

The mortality rate is 20% to 40% in cases of cerebral malaria. It is highest (80%) when there is a combination of coma and convulsions. There are few or no residua in the patients who recover.

Treatment

Cerebral malaria is a true medical emergency. In critically ill patients, treatment includes chloroquine, usually given by intramuscular injection, and quinine (or quinidine) given intravenously. In less severe cases, chloroquine alone can be used. If infection occurs in an endemic area of chloroquine-resistant falciparum malaria (now most areas of the world except parts of Central America, Mexico, the Caribbean, and the Middle East), quinine plus pyrimethamine-sulfadoxine (Fansidar), doxycycline, or clindamycin should be used. In Southeast Asia, where multiple drug resistance occurs, various regimens include quinine plus tetracycline, artesunate (or artemether) plus mefloquine, and mefloquine plus doxycycline. Anticonvulsants should be given to control seizures. Transfusions of whole blood or plasma may be required. Other supportive measures include reduction of fever, fluid and glucose replacement, and respiratory support. Sedation may be necessary in excited or delirious patients. The use of dexamethasone is deleterious in the treatment of cerebral malaria. Mannitol should be used for life-threatening cerebral edema. An infrequent possibly corticosteroid-responsive postmalarial encephalopathy has been described.

Trypanosomiasis

Two distinct varieties of infection with trypanosomes are recognized: the African form (sleeping sickness), which is due to infection with *Trypanosoma brucei*, and the South American form (Chagas disease), which is endemic in South America, Central America, and Mexico and is due to infection by *T. cruzi*. Chagas disease occurs as far north as southernmost Texas.

Etiology and Pathology

In the African form of the disease, the organisms retain their trypanosome form and multiply by longitudinal fission. They are transmitted from person to person by the tsetse fly, occasionally by other flies or insects, and by mechanical contact. There are two variants of the species: *T. brucei gambiense* (mid and west Africa) and *T. brucei rhodesiense* (east Africa). The pathologic changes are those of a chronic meningoencephalitis.

The organisms of South American trypanosomiasis, when found in the blood, have an ordinary trypanoform structure. They do not, however, reproduce in the blood but invade tissues and are transformed into typical leishmania parasites. These may later assume the trypanosome form and reenter the blood. The infection is transmitted from an animal host (e.g., rodents, cats, opossum, armadillo) to humans by a blood-sucking reduviid bug known as the "kissing bug."

The pathologic lesion in the nervous system is a meningoencephalitis consisting of miliary granulomas composed of proliferated microglial cells, with lymphocytic-plasmocytic perivascular and meningeal infiltrates. The organisms are present in glial and some nerve cells. The lesions are diffusely scattered throughout the nervous system and are accompanied by a patchy reaction in the meninges and parenchyma.

Symptoms and Signs

African trypanosomiasis (sleeping sickness) passes through two indistinct stages: febrile (hemolymphatic) and lethargic (meningoencephalitic). The incubation period is variable. In some cases, symptoms may have their onset within 2 weeks of the infection. In others, it may be delayed for months or years. The Rhodesian (east African) form usually has an acute to subacute course, whereas the Gambian (west African) disease is usually chronic. The first stage of the disease is characterized by a remitting fever, exanthems, lymphadenitis, splenomegaly, arthralgia, myalgia, and asthenia. During this period, which may last for several months or years, the organisms are present in the blood. The first stage may pass imperceptibly into the second, in which the previous symptoms are exaggerated and involvement of the nervous system is evident in the form of tremors, incoordination, convulsions, paralysis, confusion, headaches, apathy, insomnia or somnolence, and, finally, coma. There is progressive weakness with loss of weight. If the condition is untreated, death usually ensues within a year after the appearance of cerebral symptoms. Death from intercurrent infection is common.

In South American trypanosomiasis, the acute stage generally lasts about 1 month and is characterized by fever; conjunctivitis; palpebral and facial edema; enlargement of the lymph nodes, liver, and spleen; and, rarely, an acute encephalitis. During this stage, trypanosomes are present in the blood, and the leishmaniform bodies are seen in the tissue. The chronic stage is characterized by evidence of involvement of the viscera, particularly the heart and gastrointestinal tract. Neurologic involvement is rare and may be diffuse (mental alterations, seizures, choreoathetosis) or focal (hemiplegia, ataxia, aphasia). The disease is slowly progressive, with occasional acute exacerbations associated with fever. Death usually ensues within a few months or years.

Laboratory Data

Some degree of anemia is common in all forms of trypanosomiasis. The erythrocyte sedimentation rate, liver function tests, serum globulin fraction, and serum IgM may be increased. There is a lymphocytic pleocytosis in the CSF, increased protein content, increased gamma globulin fraction, and increased IgM.

Diagnosis

The diagnosis depends on the development of characteristic symptoms in residents of regions in which forms of the disease are endemic. The diagnosis is established by the demonstration of organisms in the blood or CSF, in material obtained from a biopsied lymph node, or by the inoculation of these substances into susceptible animals. Serologic and CSF antibody tests are also available.

Treatment

Melarsoprol, an organic arsenical, is effective in the treatment of *T. brucei* infections of the nervous system. Suramin or eflornithine are the drugs of choice for the acute stage. No drug treatment is established as safe and effective in chronic Chagas disease, including the CNS component. Nifurtimox or benznidazole are usually effective, however, in the acute stage of infection.

Primary Amebic Meningoencephalitis

It has been known for many years that amoebae (*Entamoeba histolytica*) may rarely invade the brain and produce circumscribed abscesses. However, free-living amoebae are the species primarily causing meningoencephalitis. *Naegleria fowleri* causes an acute meningoencephalitis, primary amebic meningoencephalitis, whereas *Acanthamoeba* species can cause both acute and granulomatous amebic meningoencephalitis. Another species, *Leptomyxid amoebae*, has caused a few cases. Amebic meningoencephalitis is rare but probably has a worldwide distribution. Most cases in the United States are reported from the Southeast.

Naegleria Infections

These infections usually occur in children or young adults who have been swimming in freshwater lakes or ponds. Inhalation of dustborne cysts may also occur in arid regions. Interestingly, the organism apparently invades the nervous system through the olfactory nerves and does not cause a systemic infection. The incubation period is several days to a week. The onset of symptoms of primary amebic meningoencephalitis is abrupt. Mild symptoms of an upper respiratory infection may occur. Fever, headache, and stiff neck are followed within 1 or 2 days by nausea and vomiting, lethargy, disorientation, seizures, increased intracranial pressure, coma, and then death.

The CSF picture is similar to that of an acute bacterial meningitis, with increased pressure, several hundred to thousands of white blood cells per cubic millimeter (primarily neutrophils), as many as several thousand red blood cells, an elevated protein content, decreased glucose, and negative Gram stain. Trophozoites may be recognized in a wet preparation of uncentrifuged CSF or with Wright or Giemsa stains. The organism can be cultured on special media or by mouse inoculation. A serologic test is available at the Centers for Disease Control and Prevention. The disease is rapidly fatal, but recovery with treatment has been reported in some cases. Amphotericin B has been used effectively alone or in combination with several drugs (rifampin, chloramphenicol, ketoconazole).

Acanthamoeba Infections

Acanthamoeba is a ubiquitous organism that can cause a subacute or chronic granulomatous amebic encephalitis as an opportunistic infection in alcoholic and immunocompromised patients. The organism probably causes a systemic infection through the respiratory tract and then seeds the brain by hematogenous spread. The meningoencephalitis may present with chronic fever and headache, followed by the gradual onset of focal neurologic signs (e.g., hemiparesis, aphasia, seizures).

with focal signature, ataxia) and abnormalities of mentation. Other signs include skin lesions, corneal ulcerations, uveitis, and pneumonitis.

There is CSF pleocytosis that is more often lymphocytic than polymorphonuclear. Protein is usually elevated, and glucose is normal or slightly decreased. Organisms occasionally may be recognized on wet preparations but have never been cultured from CSF. CT and MRI may reveal focal lesions. Biopsy is usually required for diagnosis. Several cases of acute meningoencephalitis, similar to those caused by *Naegleria*, have been reported. The disease is usually fatal. *In vitro*, the organism is usually sensitive to pentamidine, ketoconazole, flucytosine, and less so to amphotericin B.

CHAPTER 31. BACTERIAL TOXINS

JAMES R. MILLER

[Diphtheria](#)
[Tetanus](#)
[Botulism](#)
[Suggested Readings](#)

The toxins elaborated by several pathogenic bacteria have a special predilection for the nervous system. The exotoxin of the diphtheria bacillus chiefly affects the peripheral nerves, tetanus affects the activity of the neurons in the central nervous system (CNS), and botulism interferes with conduction at the myoneural junction.

DIPHTHERIA

The exotoxin of *Corynebacterium diphtheriae* is a 62,000-Da polypeptide that inhibits protein synthesis in mammalian cells by inactivation of transfer RNA translocase (elongation factor 2). It is composed of two segments: one necessary for binding to the cell and a shorter portion that then is cleaved and enters the cell. The specificity of the exotoxin for heart and peripheral nerve is attributed to receptor binding affinity at the cell surface. The exotoxin is produced by a phage, and strains of the bacterium that do not contain the phage are not pathogenic. The development of neuropathy is proportional to the severity of the primary infection. In pharyngeal infections, palatal and pharyngolaryngoesophageal paralysis is an early and prominent feature. The resistance of the other cranial nerves and brain is unexplained.

The symptoms and course of diphtheritic neuritis are considered in [Chapter 105](#).

TETANUS

Tetanus (lockjaw) causes localized or generalized spasms of muscles due to tetanospasmin, a toxin produced by the bacterium *Clostridium tetani*.

Etiology

C. tetani is commonly shed in the excreta of humans and other animals. Its spores are ubiquitous in the environment. They enter the body through puncture wounds, compound fractures, or wounds from blank cartridges and fireworks. Infection has been reported from contamination of operative wounds, burns, parenteral injections (particularly in heroin addicts), and through the umbilicus of the newborn. The mere deposition of spores of the organism is not sufficient for infection. Necrotic tissue and an associated pyogenic infection are necessary for germination of the bacteria and production of tetanospasmin.

Prevention of tetanus is accomplished by immunization with toxoid (denatured toxin). Children should be routinely immunized and boosters given every 10 years. Immediate booster immunization should be given to patients with penetrating wounds, unless a recent immunization can be documented. Immunity is not conferred by the disease, and patients should receive the toxoid and human tetanus immune globulin (HTIG), but at a different site.

Pathogenesis

Tetanospasmin is made by a single polypeptide chain of 1,315 amino acids by a large bacterial plasmid. The toxin becomes active when nicked by a serine protease into small and large chains held together by a disulfide bridge. The large chain also contains an internal disulfide bridge and appears to be necessary for penetration into the nerve cell. The small chain is responsible for toxin activity. Tetanospasmin prevents synaptic vesicles from fusing with the cell membrane and prevents the release of neurotransmitters. It appears to bind to synaptobrevin, a protein involved in the fusion process. It is active at the neuromuscular junction, autonomic terminals, and most importantly in inhibitory neurons in the CNS. The central effects usually overwhelm the peripheral effects, although autonomic dysfunction may become clinically evident. Access to the CNS is by retrograde transport in alpha motor neurons. Hematogenous spread of the toxin before neuronal transport probably accounts for generalized tetanus.

Pathology

No pathologic changes occur in the central or peripheral nervous system except those caused secondarily by anoxia or other metabolic derangement.

Incidence

The disease is found throughout the world. In the United States, it is most commonly due to infection of puncture wounds of the extremities by nails or splinters.

The incidence in developed countries has been dramatically reduced by immunization with denatured toxin (tetanus toxoid). About 100 to 200 cases probably occur in the United States each year. Worldwide, about 1 million cases occur; 50% are encountered in neonates because of nonsterile birthing technique. In the United States, the infection is most common in narcotic addicts. The narcotic is "cut" by admixing with quinine, which favors the growth of the organisms at the site of the injection.

Symptoms

The incubation period is usually between 5 and 10 days. It may be as short as 3 days or as long as 3 weeks. The severity of the disease usually is greater when the incubation period is short.

The symptoms may be localized or generalized. In the localized form, the spasms are confined to the injured limbs. This form is rare and is most commonly seen in patients who have been partially protected by prophylactic doses of antitetanic serum. When the portal of entrance is in the head (e.g., face, ear, tonsils), symptoms may be localized there (cephalic tetanus), with trismus, facial paralysis, and ophthalmoplegia.

In the generalized form, a prominent symptom is stiffness of the jaw (trismus). This is followed by stiffness of the neck, irritability, and restlessness. As the disease progresses, stiffness of the muscles becomes generalized. Rigidity of the back muscles may become so extreme that the patient assumes the position of opisthotonos. Rigidity of the facial muscles gives a characteristic facial expression, the so-called risus sardonicus. Added to the stiffness of the muscles are paroxysmal tonic spasms, which may occur spontaneously or may be precipitated by an external stimulus. Dysphagia may develop from spasm of the pharyngeal muscles; cyanosis and asphyxia may result from spasm of the glottis or respiratory muscles. Seizures may occur and are probably secondary to anoxia caused by the spasms. Temperature may be normal but more commonly is elevated to 101 to 103°F.

Laboratory Data

No specific changes are found in blood, urine, or cerebrospinal fluid (CSF).

Diagnosis

The diagnosis of tetanus is made by the characteristic signs (i.e., trismus, risus sardonicus, tonic spasms) in a patient with a wound of the skin and deeper tissues. Occasionally, however, a history of an antecedent wound is not obtained. The symptoms of strychnine poisoning differ from those of tetanus in that the muscles are relaxed between spasms and the jaw muscles are rarely involved.

Course and Prognosis

The outlook is grave in all cases of generalized tetanus. The mortality rate is over 50%. Prognosis is best when the incubation period is long. The mortality rate is reduced by the prompt administration of serum and aggressive management of pulmonary and autonomic dysfunction. In fatal cases, death usually occurs in 3 to 10 days. Death is most commonly due to respiratory compromise. In the patients who recover, there is a gradual reduction in the frequency and severity of spasms.

Treatment

The patient should be treated in an intensive care unit. The wound should be surgically cleaned. Antiserum does not neutralize toxins that have been fixed in the nervous system, but it is administered to neutralize toxin that has not yet entered the nervous system. It is customary to administer HTIG in a dose of 3000 to 6000 U intramuscularly as soon as the diagnosis is made, although as little as 500 U may be equally effective. Intrathecal HTIG has been reported to decrease mortality and probably limits transsynaptic spread of the tetanospasmin once it has gained access to the CNS. In the United States, however, HTIG contains potentially neurotoxic preservative.

Penicillin G is the most effective antibiotic for inhibiting further growth of the organisms; dirty wounds should be debrided and cleaned. Tracheostomy should be performed to ensure adequate ventilation. Diazepam is used commonly to control muscle spasms. High doses may be required, and oral dosing is preferred over intravenous administration once initial control has been achieved, because the preservative in the intravenous preparation may be toxic. Diazepam is also useful for immediate control of convulsions, but phenytoin or other suitable long-lasting anticonvulsant should be added if seizures occur. In severe cases, curarization may be necessary with use of a positive pressure respirator. Anticoagulation with heparin then should be considered because the risk of pulmonary embolism is high in curarized patients.

BOTULISM

Botulism is a poisoning by a toxin elaborated by *Clostridium botulinum*, a bacterium widely distributed in soil. Botulinum toxin impairs release of acetylcholine at all peripheral synapses, with resultant weakness of striated and smooth muscles and autonomic dysfunction.

Pathogenesis

Botulinum toxin is a 150-kDa polypeptide with structure and major sequence homologies similar to those of tetanospasmin. It is also activated by nicking of the polypeptide into a larger and smaller chain held together by a disulfide bond. After synthesis, botulinum toxin exists in a macromolecular complex with other bacteria-elaborated proteins. This complex appears necessary for pathogenicity, because the toxin alone is digested in the stomach. After absorption from the gastrointestinal tract, the toxin spreads hematogenously to peripheral presynaptic terminals where it blocks the release of acetylcholine. As with tetanus toxin, botulinum toxin appears to interfere with synaptic vesicle fusion to the presynaptic membrane. Different immune types (see below) bind to different proteins at the fusion site.

Classic botulism is caused by toxin ingested after being produced in inadequately sterilized canned or prepared food. Home-canned or -cured foods are particularly at risk, although commercial products are occasionally implicated. *C. botulinum* growth is inhibited by other common bacteria. Methods of processing that kill those bacteria, but not the resistant *Clostridium* spores, favor germination and growth of the botulinum organism. Infantile botulism, however, is caused by toxin produced by bacteria growing in the intestine.

Six immunologic types of *C. botulinum* have been identified. Human botulism usually results from toxin produced by types A, B, and E. Types A and B botulism follow the eating of tainted food; the same types have been implicated in infantile botulism. Type E is associated with fish and marine mammal products.

The toxin is thermolabile and is easily destroyed by heat. Botulism usually occurs when the preserved food is served uncooked and the rancid taste is obscured by acid dressings.

Symptoms and Signs

The symptoms of poisoning by the toxin appear 6 to 48 hours after the ingestion of contaminated food and may or may not be preceded by nausea, vomiting, or diarrhea. The initial symptom is usually difficulty in convergence of the eyes, soon followed by ptosis and paralysis of the extraocular muscles. The pupils are dilated and may not react to light. The ocular symptoms are followed by weakness of the jaw muscles, dysphagia, and dysarthria. The weakness spreads to involve muscles of the trunk and limbs. Smooth muscle of the intestines and bladder is occasionally affected, with resulting constipation and retention of urine. Mentation is usually preserved, but convulsions and coma may develop terminally. Blood and CSF are normal. In severe cases, symptoms may be those of cardiac or respiratory failure.

Infantile botulism occurs in the first year of life, with a peak incidence at 2 to 4 months of age. About 30% of infantile botulism in the United States appears to follow the ingestion of honey. A period of constipation of about 3 days is followed by the acute onset of hypotonia, weakness, dysphagia, poor sucking, and ptosis. It is estimated that 5% of cases of sudden infant death syndrome are due to botulism, although the true frequency is unknown.

Diagnosis

The diagnosis is not difficult when several members of one household are affected or if samples of the contaminated food can be obtained for testing. Bulbar palsy in acute anterior poliomyelitis can be excluded by the normal CSF. Myasthenia gravis may be simulated, especially if the pupils are not clearly affected in a sporadic case of botulism. In myasthenia gravis, there is a decremental electromyographic response to repetitive stimulation of nerve, but in botulism there is an increasing response that resembles the Lambert-Eaton syndrome.

Course

The course depends on the amount of toxin absorbed from the gut. The symptoms are mild and recovery is complete if only a small amount is absorbed. When large amounts are absorbed, death usually occurs within 4 to 8 days from circulatory failure, respiratory paralysis, or the development of pulmonary complications.

Treatment

Botulism can be prevented by taking proper precautions in the preparation of canned foods and discarding (without sampling) any canned food with a rancid odor or in which gas has formed. The toxin is destroyed by cooking. There are no established means of preventing infant botulism, although honey should not be given in the first year of life.

Patients should be given botulinum antitoxin. In the United States, trivalent (A, B, E) antitoxin is available from the Centers for Disease Control and Prevention. The stomach should be lavaged gently and the lower gastrointestinal tract thoroughly cleansed by enemas and cathartics not containing magnesium. Respiratory assistance may be required. Feedings should be by enteral tube. Some beneficial results on weakness have been reported with the use of guanidine, but the evidence is conflicting. 2,4-Diaminopyridine has also been used.

CHAPTER 32. REYE SYNDROME

DARRYL C. DE VIVO

[Suggested Readings](#)

In 1963, Reye et al. reported clinical and pathologic observations in 21 children with encephalopathy and fatty changes in the viscera. Since then, the number of reported cases has increased all over the world with unexplained fluctuations in incidence from decade to decade. The disorder also affects infants and adults, although rarely. White children in suburban or rural environments seem to be more susceptible than urban black children.

Reye syndrome is usually associated with influenza B epidemics or sporadic cases of influenza A and varicella. Characteristically, the encephalopathy develops 4 to 7 days after the onset of the viral illness. It is invariably heralded by recurrent vomiting and often followed by somnolence, confusion, delirium, or coma. These children have frequently been treated with antiemetics, aspirin, or acetaminophen. Epidemiologic studies have shown a statistical association between the ingestion of aspirin-containing compounds and the development of Reye syndrome. These studies, however, do not prove a causal relationship.

Pathologic and metabolic observations suggest a primary injury to mitochondria throughout the body with prominent involvement of the liver and brain. The primary injury may be compounded by many associated insults, including hyperpyrexia, hypoglycemia, hypoxia, hyperammonemia, free fatty acidemia, systemic hypotension, and intracranial hypertension. An appropriate clinical history, characteristic neurologic findings, absence of any other explanation for the encephalopathy, and distinctive laboratory abnormalities are usually sufficient for establishing the diagnosis. Important laboratory abnormalities include elevations of blood ammonia, lactate, and serum transaminases and prolongation of the prothrombin time. Cerebrospinal fluid examination and computed tomography are normal. The electroencephalogram is diffusely abnormal, occasionally displaying paroxysmal epileptiform activity in the more severely ill patients.

Many other conditions can present a similar clinical picture. The differential diagnosis includes bacterial meningitis, viral encephalitis, drug intoxication (e.g., aspirin, valproic acid, and amphetamines), and other metabolic disorders (e.g., inherited defects of fatty acid oxidation, branched-chain amino acid metabolism, and the Krebs-Henseleit urea cycle). Recurrent attacks of a Reye-like syndrome imply an underlying metabolic disorder. The current mainstay of treatment is intensive supportive care. Most patients recover completely within a week after onset.

CHAPTER 33. PRION DISEASES

BURK JUBELT

[Kuru](#)
[Creutzfeldt-Jakob Disease](#)
[Gerstmann-Sträussler-Scheinker Disease](#)
[Fatal Familial Insomnia](#)
[Suggested Readings](#)

In previous editions of this textbook, the section on viral diseases included a discussion of “unconventional viruses” that cause scrapie, a disease of sheep, and several human diseases: kuru, Creutzfeldt-Jakob disease (CJD), Gerstmann-Sträussler syndrome (GSS), and fatal familial insomnia (FFI). All these conditions are rare, but among them, CJD is the most common ([Table 33.1](#)). All have characteristic pathologic changes that led to the early designation of *spongiform encephalopathy*. These diseases are now called *prion diseases*. The name has been changed to comply with changing concepts of the agent, which, like a virus, is transmissible. It differs from any known virus, however, because the molecule does not include any detectable nucleic acid. It is resistant to heat, ultraviolet light, and ionizing radiation, which modify nucleic acids. However, the infectivity of the agent is susceptible to treatments that denature proteins (sodium dodecyl sulfate, phenol). The neologism was taken from the two key features of the agent, protein and infectious. Because these agents appear to differ from viruses and because there now is some understanding of the pathogenesis of these diseases, a separate chapter on the prion diseases is appropriate.

Syndrome	Number of Patients
Creutzfeldt-Jakob disease	278
Sporadic	234
Familial	36
Iatrogenic	8
Kuru	18
Gerstmann-Sträussler-Scheinker syndrome	2

Modified from Brown P, Gibbs CJ Jr, Rodgers-Johnson P, et al. Human spongiform encephalopathy: the NIH series of 300 cases of experimentally transmitted disease. *Ann Neurol* 1994;35:513-529.

TABLE 33.1. RELATIVE FREQUENCY OF HUMAN PRION DISEASE: TISSUES REFERRED FOR TRANSMISSION TO PRIMATES

The human prion protein is encoded by a gene currently designated *PRNP* on the short arm of chromosome 20. The prion protein (PrP) is found in two isoforms. One is the normal cellular form (PrP^C). The other form differs only in physical characteristics and is found in scrapie (PrP^{Sc}) and other animal prion diseases and in the human prion diseases. PrP^C is an intracellular membrane bound protein. Its normal biological function is unknown. PrP^{Sc} is found not only intracellular but also extracellular in amyloid filaments and amyloid plaques. Delineation of the nature of this new agent gained a Nobel Prize for Stanley Prusiner.

The animal prion diseases include scrapie of sheep, transmissible mink encephalopathy, chronic wasting disease of elk and mule deer, and bovine spongiform encephalopathy (BSE). Scrapie was recognized in ancient times and was considered transmissible or infectious in the 1930s. Scrapie occurs primarily in Europe but has occurred in the United States. In the last decade the prion diseases have become a public health problem because of the epidemic of BSE (“mad cow” disease) in Great Britain. BSE occurred because cattle were fed scrapie-contaminated meat-and-bone meal. This same mechanism has caused a disease in domestic cats (feline spongiform encephalopathy) and felines in zoos. In addition, atypical CJD (“new variant” CJD) has affected young adults in Great Britain and France infected with the BSE agent.

The human diseases can be sporadic, infectious, or genetic; 80% to 90% of CJD cases are sporadic. Iatrogenic CJD and familial CJD (autosomal dominant) each account for 5% to 10% of CJD cases. GSS and FFI are also genetic and rare ([Table 33.1](#)). Sporadic CJD is not spread like an ordinary infection because the agent has low infectivity. Those with prior head and neck trauma and medical personnel may be at higher risk because of increased exposure to the agent. CJD has been transmitted by implanting electrodes or transplanting corneas from affected patients. Iatrogenic disease has also occurred with dura mater grafts and administration of growth hormone extract prepared from pooled human pituitary glands. Gajdusek and colleagues found that all these diseases can be transmitted to chimpanzees or guinea pigs (Brown et al., 1994; see [Table 33.1](#)). In that sense the diseases are infectious. Mutations in the *PrP* gene cause the inherited diseases, which are therefore both heritable and transmissible.

There is now debate about nomenclature, whether we should continue to refer to the diseases by the original clinicopathologic designations or whether they should all be lumped as “prion disease” and identified by the specific mutation identified. The latter group points to people in the same family who have different clinical syndromes. They have also identified PrP mutations in atypical syndromes, such as dementia resembling Alzheimer disease, or spastic paraplegia.

The former group, on the other hand, points to a strong tendency for specific mutations to be associated with specific clinical syndromes ([Table 33.2](#)) and to differences in transmissibility of the different clinical syndromes. For instance, Brown and colleagues (1994) found that all iatrogenic cases were transmitted to chimpanzees, as were 90% of sporadic CJD but only 68% of the familial cases; 95% of the cases of kuru were transmitted, but only two of four cases of GSS were transmitted. Additional molecular techniques may be useful for categorizing the prion diseases. Proteinase K digestion of CJD brain homogenates followed by Western blot analysis has demonstrated the presence of protease-resistant prion proteins (PrP^{res}) of different patterns (based on the size and ratio of differently glycosylated isoforms). Thus far, four distinct patterns have been recognized: types 1 and 2 primarily in sporadic CJD; type 3, iatrogenic CJD; type 4, new variant. The prion proteins of the other prion diseases have not as yet been adequately analyzed by this technique.

Codon No.	Normal Amino Acids (s)	Mutant Amino Acid (s)	Familial Prion Disease
51-91	5 octapepeats	Additional 2-9 octapepeats	CJD
178	Asp	Asn	CJD
180	Val	Ile	CJD
200	Glu	Lys	CJD
210	Val	Ile	CJD
232	Met	Arg	CJD
102	Pro	Leu	GSS
105	Pro	Leu	GSS
117	Ala	Val	GSS
145	Tyr	Stop	GSS
198	Phe	Ser	GSS
217	Glu	Arg	GSS
129	Val or Met	Val	179 ^{Met} CJD
		Met	178 ^{Met} FFI

^aOther mutations have been described but only in single cases. CJD, Creutzfeldt-Jakob disease; GSS, Gerstmann-Sträussler-Scheinker syndrome.

TABLE 33.2. MUTATIONS IN THE PRION PROTEIN GENE ASSOCIATED WITH FAMILIAL PRION DISEASES^a

KURU

This progressive and fatal disorder occurs exclusively among natives (Fore people) of the New Guinea Highlands. It is manifested by incoordination of gait, severe trunk and limb ataxia, abnormal involuntary movements resembling myoclonus or chorea, convergent strabismus, and, later in the disease, dementia. The illness

terminates fatally in 4 to 24 months. Cannibalism is considered the principal mode of transmission, affecting children, adolescents, and adult women. Since this practice was eliminated in the 1950s, the disease now is rare and affects only older adults of both sexes. Neuropathologic changes include widespread neuronal loss, neuronal and astrocytic vacuolization, and astrocytic proliferation. Amyloid plaques containing the abnormal prion protein (PrP) were first described in kuru, and called kuru plaques. These pathologic changes are most prominent in the cerebellum, where gross atrophy may be seen. The cerebrum and brainstem are involved to a lesser degree.

The similarity between the clinical and neuropathologic manifestations of kuru and those seen in scrapie-afflicted sheep led Gajdusek and Gibbs to infect higher primates with brain suspensions. Inoculation of chimpanzees was followed by the appearance of a kuru-like disease 14 months to several years later. Kuru was the first human-transmissible spongiform encephalopathy (prion disease) to be recognized. Gajdusek was awarded a Nobel Prize for this work.

CREUTZFELDT-JAKOB DISEASE

In 1920 and 1921, Creutzfeldt and Jakob described a progressive disease of the cortex, basal ganglia, and spinal cord that developed in middle-aged and elderly adults. CJD (spastic pseudosclerosis, corticostriatal degeneration) was the second human prion disease to be recognized. CJD occurs throughout the world but is relatively rare, with an incidence of about 1 case per 1 million people annually. This incidence is the same throughout the world except for the high incidence among Libyan Jews in Israel and in a few populations elsewhere. The disease affects mainly middle-aged and older individuals, with an average age at onset of about 60 years.

Pathology

The pathologic condition is essentially degenerative with grossly evident cerebral atrophy. Microscopic findings are similar to other prion diseases with neuronal loss, astrocytosis, and the development of cytoplasmic vacuoles in neurons and astrocytes (status spongiosus, [Fig. 33.1](#)). Amyloid plaques that contain the abnormal PrP are found in the areas of infected tissue in most cases. There is no inflammation. The cortex and basal ganglia are most affected, but all parts of the neuraxis may be involved. Early lesions are more severe in the gray matter.

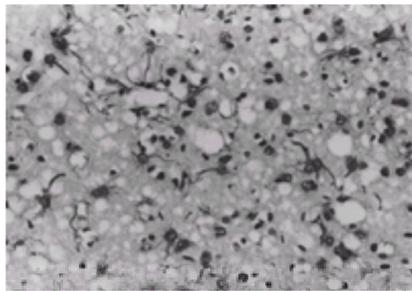

FIG. 33.1. Creutzfeldt-Jakob disease. Section from cortex showing status spongiosus of the neuropil, loss of neurons, and prominent astrocytosis. Phosphotungstic acid hematoxylin stain, $\times 120$. (Courtesy of Dr. Mauro C. Dal Canto.)

Symptoms and Signs

The clinical features include the gradual onset of dementia in middle or late life, but occasionally in young adults. Vague prodromal symptoms of anxiety, fatigue, dizziness, headache, impaired judgment, and unusual behavior may occur. Once memory loss starts, it progresses rapidly, and other characteristic signs appear, sometimes abruptly. The most frequent signs, aside from dementia, are those of pyramidal tract disease (weakness and stiffness of the limbs with accompanying reflex changes), extrapyramidal signs (tremors, rigidity, dysarthria, and slowness of movements), and myoclonus, which is often stimulus sensitive. Other signs include amyotrophy, cortical blindness, seizures, and those of cerebellar dysfunction ([Table 33.3](#)). None of the usual signs of an infection is seen.

	Percentage of Patients	
	At Onset	Later
Mental deterioration	69	100
Memory loss	48	100
Behavioral change	29	57
Aphasia, agnosia	15	73
Cerebellar signs	33	71
Visual, oculomotor signs	19	42
Headache	11	58
Sensory change	6	11
Involuntary movements	4	91
Myoclonus	1	28
Tremor, other	3	36
Pyramidal signs	2	62
Extrapyramidal signs	0.5	56
Lower motor neuron signs	0.5	12
Seizures	0	19
Pseudotumor signs	0.5	7
Periodic electroencephalogram	0	60

TABLE 33.3. 232 EXPERIMENTALLY TRANSMITTED CASES OF SPORADIC CREUTZFELDT-JAKOB DISEASE

Laboratory Data

Routine blood counts and chemistries are normal. Routine cerebrospinal fluid (CSF) tests are usually normal, although the protein content may rarely be elevated. In 1986, Harrington et al. described two abnormal proteins in the CSF of CJD patients on two-dimensional gel electrophoresis. These proteins were also found in acute herpes simplex encephalitis. This assay did not become generally used because of its difficulty. Ten years later, studies from the same laboratory reported the sequence of these two proteins, which matched that of brain proteins known as 14-3-3 neuronal proteins that may play a role in conformational stabilization of other proteins. An immunoassay for the 14-3-3 protein was positive in 96% of CJD CSF samples. The assay was also positive in other diseases with acute massive neuronal dysfunction, especially herpes simplex encephalitis and acute infarction. Still, in the appropriate clinical setting, the immunoassay for the 14-3-3 protein is a highly supportive diagnostic test. The electroencephalogram (EEG) may also be of diagnostic value because periodic complexes of spike or slow wave activity at intervals of 0.5 to 2.0 seconds are characteristic in the middle and late stages of the disease ([Fig. 33.2](#)). Computed tomography and magnetic resonance imaging may reveal cerebral atrophy late in the course of the disease. In a few cases, increased signal intensity on T2-weighted magnetic resonance imaging has been seen in the cortex and basal ganglia.

FIG. 33.2. Creutzfeldt-Jakob disease. Record of a 65-year-old man shows spikes of sharp waves at intervals of 0.7 seconds throughout the recording. Such periodicity with 0.5- to 2.0-second intervals occurs in the middle and late stages and may be absent in the early stages of the disease.

Diagnosis and Differential Diagnosis

A definitive diagnosis of CJD can only be made by neuropathologic, immunologic, or biochemical examination of the brain. In typical cases (dementia, myoclonus, periodic EEG), the diagnosis can be made clinically. However, the diagnosis is difficult to make in atypical cases (no myoclonus, absence of periodic EEG). In the atypical cases, the diagnosis of Alzheimer disease is often made. Other degenerative diseases, such as Pick disease, corticobasal ganglionic degeneration, familial myoclonic dementia, and multisystem atrophy, and lithium toxicity may also be considered. The CSF test for the 14-3-3 protein may clarify the atypical cases. If not, brain biopsy is needed for evaluation of pathology or demonstration of protease-resistant PrP.

Course and Prognosis

The disease is fatal within 1 year in 90% of patients. Rarely, the course may be prolonged over several years. There is no specific treatment.

Transmissibility and Biohazard Potential

As with kuru, neurologic illness can be produced in primates by the inoculation of brain suspensions prepared from the brains of Creutzfeldt-Jakob patients. The mode of transmission of sporadic CJD is unknown. The agent has been detected in most internal organs (lung, liver, kidney, spleen, and lymph nodes), cornea, and blood but has not been detected in saliva or feces. One isolation from urine may have been a contaminate. These findings suggest a lack of significant spread by respiratory, enteric, or sexual contact. Failure to find an increased incidence in spouses also suggests that these usual modes of transmission of infections are not of major importance. Isolation of Creutzfeldt-Jakob patients does not seem necessary except for body fluids, as in the precautions taken with serum hepatitis. Human-to-human transmission has been reported after corneal transplantation, use of inadequately sterilized stereotactic brain electrodes, parenteral administration of human growth hormone preparations, and the use of human dura mater grafts. Caution must be exercised in operating rooms and pathology laboratories and in the preparation of brain-derived biologicals. Medical personnel should avoid contact of open sores or conjunctiva with these tissues. Caution should be taken to avoid accidental percutaneous exposure to CSF, blood, or tissue. Because the prion agents are highly resistant to ordinary physical or chemical treatment (routine autoclaving or formalin), special autoclaving procedures or special inactivating agents, including sodium hypochlorite (household bleach), are required.

New Variant Creutzfeldt-Jakob Disease

In 1996, 10 cases of “new variant” CJD were reported in Great Britain. These cases were unusual both clinically and pathologically in that they shared many characteristics normally associated with kuru. Symptoms started before age 40; several cases occurred in teenagers. Clinical findings included ataxia and behavioral changes. Myoclonic jerks and the characteristic EEG abnormalities were not seen. The course was slower than conventional CJD, lasting up to 22 months. At least 22 cases have now been reported. The pathologic changes were also unusual with minimal spongiosis but prominent plaque formation in the cerebellum and cerebrum. Transmission experiments of both BSE and new variant CJD brain tissue to animals confirmed the similar strain characteristics. Molecular analysis (proteinase K digestion) of brain homogenates from these new variant CJD cases revealed a Western blot pattern similar to that of BSE rather than that of sporadic CJD.

GERSTMANN-STRAÜSSLER-SCHEINKER DISEASE

GSS disease is the third human disease caused by a prion agent. It has also been referred to as the Gerstmann-Sträussler syndrome. GSS is an autosomal dominant familial disease ([Table 33.2](#)). It has a lengthy course with a range of 2 to 10 years. Clinically, it begins with ataxia; dementia eventually supervenes. Brainstem involvement leads to symptoms suggesting olivopontocerebellar degeneration. Less common is the “telencephalic” form with dementia, parkinsonism, and pyramidal tract signs and a variant form with neurofibrillary tangles. Pathologically there is usually spongiform change and prominent amyloid plaque deposition in the cerebellum, cerebrum, and basal ganglia. There is also degeneration of the spinocerebellar and corticospinal tracts. The EEG usually does not show periodicity, only diffuse slowing. As with CJD, there is no treatment.

FATAL FAMILIAL INSOMNIA

FFI is an autosomal dominant disease with a course of 7 to 36 months and an age at onset between 18 to 61 years. Familial thalamic dementia or degeneration appears to be the same disease. The patients have progressive insomnia and dysautonomia (hyperhidrosis, tachycardia, tachypnea, hyperthermia, hypertension) and may develop pyramidal and cerebellar signs, dementia, and myoclonus. However, there may be diverse phenotypic expression of the disease, even in the same family. Some patients do not develop insomnia until later stages. Other patients may present with clinical features of CJD. The EEG usually shows diffuse slowing; periodicity has been described only rarely. These patients have a mutation of the *PrP* gene at codon 178, coupled with a methionine at codon 129 ([Table 33.2](#)). Patients who are homozygous for methionine at codon 129 have a much more rapid course than those who are heterozygous. Pathologically, there is prominent neuronal loss and gliosis in the thalamus with little to no spongiform change. Patients with long duration or atypical presentations are more likely to have widespread lesions in cerebral cortex, basal ganglia, brainstem, and cerebellum. Because the clinical manifestations of FFI vary, genotyping is crucial for confirming the diagnosis. There is no specific treatment at this time.

CHAPTER 34. WHIPPLE DISEASE

ELAN D LOUIS

[Epidemiology](#)
[Systemic Disease](#)
[Neurologic Manifestations](#)
[Laboratory Data](#)
[Treatment](#)
[Suggested Readings](#)

Whipple disease was originally described as a gastrointestinal disorder with arthralgia. It is caused by a bacilliform bacterium, and infection is evident in many organs, including but not limited to the intestinal tract, heart, lungs, liver, kidneys, and brain. Polymerase chain reaction (PCR) analysis of DNA coding for bacterial ribosomal RNA has led to characterization of the Whipple organism. The organism, *Tropheryma whippelii*, belongs to the Actinomycetaceae family of bacteria. The organism, difficult to culture, has been propagated in cell culture in macrophages that had been deactivated by interleukin-4. Whipple disease has not been reproduced in animals.

The bacillus is rod shaped, 0.2 μm wide by 1.0 to 2.0 μm long, and large enough to be seen under light microscopy. The three-layered cell wall may stain either gram-positive or -negative but more often gram-positive. Bacilli appear both extracellularly and intracellularly in many cell types. The organism produces a cellular rather than a humoral immune response, and this is predominated by macrophage recruitment. Infected macrophages stain strongly with the periodic acid–Schiff (PAS) reaction. Examination by electron microscopy of these macrophages demonstrates that the areas of intense PAS staining are packed with bacilli. These areas usually have a distinctive sickle shape, and the macrophages are often referred to as sickleform particle-containing cells.

EPIDEMIOLOGY

The epidemiology of Whipple disease is not well understood. There seems to be a preponderance of the systemic disorder in males and in whites. Among the nearly 700 patients analyzed by Dobbins (1987), 86.4% were male and 97.8% were white. Individuals who worked with soil or animals accounted for two of every three cases. DNA of the organism was detected in five different sewage treatment plants in Germany, providing the first documented encounter with the organism in the environment and supporting the notion of an environmental source of infection. The route of infection is not known, although an oral route is suspected. There have been reports of clusters of affected individuals within families.

SYSTEMIC DISEASE

Symptoms include weight loss (usually 20 to 30 pounds, occasionally as much as 100 pounds), abdominal pain (often nondescript epigastric pain), diarrhea (often with steatorrhea), and arthritis (often migratory and involving large joints). In 50% of patients, arthritis precedes the intestinal manifestations by 10 to 30 years. Other systemic manifestations include low-grade fever, lymphadenopathy, and increased skin pigmentation.

In systemic disease, blood studies may reveal anemia and hypoalbuminemia. Intestinal absorption studies often reveal steatorrhea and diminished xylose absorption. Diagnosis, however, is usually made by small intestinal biopsy to demonstrate the PAS-staining macrophages. Because PAS-positive macrophages may be found in other diseases and in other tissues of apparently normal individuals, confirmation of the diagnosis is facilitated by detection of the actual bacillus with electron microscopy or by PCR analysis of infected tissue. If intestinal biopsy is PAS-negative, multiple biopsies with electron microscopic examination may be required to establish the diagnoses.

NEUROLOGIC MANIFESTATIONS

In 5% of patients with Whipple disease, the first symptoms are neurologic, but central nervous system (CNS) symptoms may eventually occur in 6% to 43% of cases. Asymptomatic CNS infection occurs as well. In some cases, CNS disease may occur without evidence of infection elsewhere. Neurologic symptoms and signs are protean. Louis et al. (1996) reviewed reports of 84 cases of CNS Whipple disease. The following signs were most prevalent: cognitive changes (including abnormalities of orientation, memory, or reasoning, 71%), supranuclear gaze palsy (more often vertical than horizontal, 51%), altered level of consciousness (including somnolence, lethargy, stupor, or coma, 50%), psychiatric signs (including depression, euphoria, anxiety, psychosis, or personality change, 44%), upper motor neuron signs (37%), and hypothalamic manifestations (including polydipsia, hyperphagia, change in libido, amenorrhea, changes in sleep–wake cycle, insomnia, 31%). Other signs in 20% to 25% of cases included cranial nerve abnormalities, myoclonus, seizures, and ataxia ([Table 34.1](#)). The combination of pendular vergence oscillations of the eyes in synchrony with masticatory myorhythmia has been termed “oculomasticatory myorhythmia.” When there is myorhythmia of skeletal muscles as well, the term “oculofacial skeletal myorhythmia” has been used. Although these forms of myorhythmia are pathognomonic of CNS Whipple disease, they were noted in only 20% of patients. The classic triad of dementia, supranuclear gaze palsy, and myoclonus was noted in only 15% of cases.

Signs	Percent
Cognitive change	71
Supranuclear gaze palsy	51
Altered level of consciousness	50
Psychiatric signs	44
Upper motor neuron signs	37
Hypothalamic manifestations	31
Cranial nerve abnormalities	25
Myoclonus	25
Seizures	23
Ataxia	20
Oculomasticatory myorhythmia or oculo-facial-skeletal myorhythmia	20
Sensory deficits	12

TABLE 34.1. NEUROLOGIC SIGNS IN 84 CASES OF CENTRAL NERVOUS SYSTEM WHIPPLE DISEASE

LABORATORY DATA

In CNS Whipple disease, over half of the patients show a focal abnormality on computed tomography or magnetic resonance imaging, ranging from a small focal lesion without mass effect to large numbers of enhancing lesions with mass effect. However, these abnormalities are not specific. A low level cerebrospinal fluid pleocytosis (mean, 91 leukocytes/ μL ; range, 5 to 900) is found in half the patients with the CNS disorder, and cerebrospinal fluid protein is elevated in half (mean, 75 mg/dL; range, 47 to 158). When CNS Whipple disease is suspected from clinical manifestations, the diagnosis may be confirmed by biopsy of any infected tissue with identification of bacteria or PCR analysis. In Louis et al.’s review (1996), biopsy was a sensitive technique; 70% of intestinal biopsies and 89% of all tissue biopsies (including small bowel, brain, lymph node, vitreous fluid) were positive. Factors that contributed to a negative small-bowel biopsy included absence of chronic diarrhea, lack of endoscopic guidance, specimens not examined by electron microscopy, and biopsy not repeated at least once if initially negative.

TREATMENT

If untreated, CNS disease may have a fulminant course, progressing to death within 1 month. Even when treated, the prognosis is uncertain. Many antibiotics have been used with variable success. The most commonly used agents have been tetracycline, penicillin, and trimethoprim-sulfamethoxazole (TMP-SMX). Many authors recommend oral TMP-SMX, but not all patients respond, and intravenous ceftriaxone or TMP-SMX appears to be more effective. The optimum duration of treatment of acute infection is not known nor is the length of follow-up treatment. Treatment of CNS disease must be prolonged because recurrence has followed months of

treatment and apparent disappearance of disease.

SECTION IV. VASCULAR DISEASES

CHAPTER 35. PATHOGENESIS, CLASSIFICATION, AND EPIDEMIOLOGY OF CEREBROVASCULAR DISEASE

RALPH L. SACCO

[Definition and Nosology](#)
[Vascular Anatomy](#)
[Physiology](#)
[Pathogenesis and Classification](#)
[Stroke Epidemiology](#)
[Suggested Readings](#)

Stroke continues to be a major public health problem that ranks in the top four causes of death in most countries and is responsible for a large proportion of the burden of neurologic disorders. More often disabling than fatal, stroke is the leading cause of severe neurologic disability and results in enormous costs measured in both health-care dollars and lost productivity. Major strides have been made in understanding the epidemiology, etiology, and pathogenesis of cerebrovascular disease and have led to new approaches to diagnosis and treatment.

DEFINITION AND NOSOLOGY

In the broadest sense, the World Health Organization has defined stroke as “rapidly developing clinical signs of focal (at times global) disturbance of cerebral function, lasting more than 24 hours or leading to death with no apparent cause other than that of vascular origin.” By conventional clinical definitions, if the neurologic symptoms continue for more than 24 hours, a person is diagnosed with stroke; otherwise, a focal neurologic deficit lasting less than 24 hours is defined as a transient ischemic attack (TIA). For symptoms that exceed 24 hours and resolve within 3 weeks, another category, reversible ischemic neurologic deficit, has been used to define what is nothing other than a minor stroke. Such terms defined by the duration of neurologic symptoms are being redefined with the more widespread use of sensitive brain imaging that has shown that patients with fleeting symptoms can be found to have an imaged stroke (i.e., cerebral infarction transient symptoms). The most recent definition of stroke for clinical trials has required either symptoms lasting more than 24 hours or imaging of an acute clinically relevant brain lesion in patients with rapidly vanishing symptoms. The duration and severity of the syndrome then can be used to classify patients as those with minor or major stroke. The use of the term “brain attack,” which may lack specificity, has been championed by the educational campaigns of national health organizations to help inform the public about the urgency of stroke.

In addition to duration, stroke is classified by the pathology of the underlying focal brain injury into either infarction or hemorrhage. Intracranial hemorrhage can be subdivided into two distinct types based on the site and vascular origin of the blood: subarachnoid, when the bleeding originates in the subarachnoid spaces surrounding the brain, and intracerebral, when the hemorrhage is into the substance or parenchyma of the brain. Ischemic infarction can be classified into various subgroups based on the mechanism of the ischemia and the type and localization of the vascular lesion.

The cardinal feature of stroke is the sudden onset of neurologic symptoms. “Silent stroke” may occur without apparent clinical manifestations, however, because either the patient and family are unaware of minor symptoms or a so-called silent area of brain has been affected. Premonitory stroke symptoms are not always found; fewer than 20% of stroke patients have a prior TIA. Focal premonitory symptoms, when present, usually predate infarction rather than hemorrhage. When they occur, they may be so nonspecific that they are not recognized as signs of an impending stroke.

The neurologic symptoms often reflect the location and size of stroke, but they usually cannot be used to definitively differentiate the type of stroke. When headache, vomiting, seizures, or coma occur, however, hemorrhage is more likely than infarction. Specific neurologic symptoms that may occur in isolation or in various combinations include loss of vision (hemianopia), double vision, weakness or sensory loss on one side of the body, dysarthria, alteration in higher cognitive functions (dysphasia, confusion, spatial disorientation, neglect, dysmemory), difficulty walking, headache, or unilateral deafness. Part of the challenge is to localize precisely the affected anatomic region and the corresponding vascular territory based on the clinical symptoms and signs. This step is reviewed in [Chapter 38](#) in connection with the syndromes of specific cerebral arteries. A prerequisite, however, is a sound understanding of the anatomy of the vascular supply of the brain.

VASCULAR ANATOMY

The brain is perfused by the carotid and vertebral arteries, which begin as extracranial arteries off the aorta or other great vessels and course through the neck and base of the skull to reach the intracranial cavity ([Fig. 35.1](#)). The carotid and its branches are referred to as the anterior circulation and the vertebrobasilar as the posterior circulation.

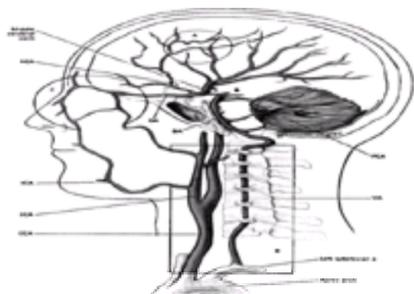

FIG. 35.1. Arterial supply to the brain with enlarged detail of the sites of anastomosis in the cerebral circulation. **A:** Over the convexity, subarachnoid interarterial anastomoses link the middle (MCA), anterior (ACA), and posterior cerebral arteries (PCA) through the border zone. **B:** The circle of Willis provides communication between the anterior and posterior cerebral circulation via the anterior and posterior communicating arteries. **C:** Through the orbit, anastomoses occur between the external (ECA) and internal carotid arteries (ICA). **D:** Extracranial anastomoses connect the muscular branches of the cervical arteries to the vertebral arteries (VAs) and the ECAs. OA, ophthalmic artery; BA, basilar artery; CCA, common carotid artery.

The right common carotid originates from the bifurcation of the innominate, whereas the left originates directly from the aortic arch. The internal carotid arteries stem from the common carotid, usually at the level of the upper border of the thyroid cartilage at the fourth cervical vertebrae, give no branches in the neck and face, and enter the cranium through the carotid canal. The four main segments of the internal carotid are cervical, petrous, cavernous, and supraclinoid. The siphon is the term used to describe the series of turns made by the cavernous and supraclinoid segments. The internal carotid ends by dividing into the middle and anterior cerebral arteries after giving off the ophthalmic, superior hypophyseal, posterior communicating, and anterior choroidal arteries. The carotid system therefore supplies the optic nerves and retina plus the anterior portion of the cerebral hemisphere, which comprises the frontal, parietal, and anterior temporal lobes. In as many as 15% of adults, the posterior cerebral artery also arises directly from the internal carotid artery so that the entire cerebral hemisphere (including the occipital lobe) is supplied by the internal carotid artery.

The middle cerebral artery is the largest branch of the internal carotid artery and appears almost as a direct continuation. It begins as a single trunk (stem or M1 segment) passing laterally to the sylvian fissure, where it becomes the M2 or insular segment, from which the 12 cerebral surface branches originate. The stem

usually ends in either a bifurcation into the upper and lower division or a trifurcation into three major trunks (upper, middle, and lower divisions). The cortical divisions supply almost the entire cortical surface of the brain, including insula, operculum, and frontal, parietal, temporal, and occipital cortices; the frontal pole, the superior and extreme posterior rim of the convex surface, and medial cortical surfaces are not supplied by the middle cerebral artery.

The middle cerebral artery stem gives rise to the medial and lateral lenticulostriates, which supply the extreme capsule, claustrum, putamen, most of the globus pallidus, part of the head and the entire body of the caudate, and the superior portions of the anterior and posterior limbs of the internal capsule. The upper division usually gives rise to the lateral orbitofrontal, ascending frontal, precentral (pre-rolandic), central (rolandic), and anterior parietal branches, whereas the lower division usually contains the temporal polar, temporooccipital, anterior, middle, and posterior temporal branches. The posterior parietal and angular branches are more variable.

The anterior cerebral artery begins as a medial branch of the internal carotid artery, forming the proximal or A1 segment to the junction of the anterior communicating artery where it continues as the distal or A2 segment. The largest branch is known as the recurrent artery of Heubner, and several cortical branches supply the medial and orbital surfaces of the frontal lobe.

The vertebral artery usually arises from the subclavian artery, courses through the transverse foramina, pierces the dura, and enters the cranial cavity to join the contralateral vertebral artery. At the distal segment are the origin for the anterior and posterior spinal arteries and posterior inferior cerebellar artery, which supplies the inferior surface of the cerebellum. The lateral medulla is supplied by the multiple perforating branches of the posterior inferior cerebellar artery or direct medullary branches of the vertebral artery.

The basilar artery originates as the merger of the right and left vertebral arteries usually at the level of the pontomedullary junction ([Fig. 35.2](#)). Paramedian penetrators, short and long lateral circumferential penetrators, originate from the basilar artery to supply the brainstem. The anterior inferior cerebellar and superior cerebellar arteries perfuse the ventrolateral aspect of the cerebellar cortex, and the internal auditory (labyrinthine) artery arises either directly from the basilar or from the anterior cerebellar artery to supply the cochlea, labyrinth, and part of the facial nerve.

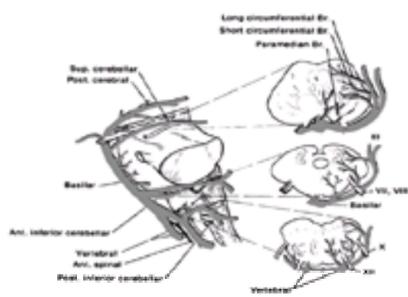

FIG. 35.2. Vascular supply of the brainstem.

The basilar artery usually terminates into the posterior cerebral arteries. A series of penetrators (posteromedial, thalamoperforates, thalamogeniculate, tuberothalamic) arises from the posterior communicating and posterior cerebral artery to supply the hypothalamus, dorsolateral midbrain, lateral geniculate, and thalamus. The posterior cerebral artery supplies the inferior surface of the temporal lobe and medial and inferior surfaces of the occipital lobe, including the lingual and fusiform gyri.

A rich anastomotic network includes various extracranial intercommunicating systems, intracranial connections through the circle of Willis, and distal intracranial connections through meningeal anastomoses throughout the border zones over the cortical and cerebellar surfaces. These networks protect the brain by providing alternate routes to circumvent obstructions in the main arteries. Obstruction of the extracranial internal carotid may remain asymptomatic if there is adequate perfusion made available through a variety of collateral pathways, such as the external carotid to the ophthalmic to the intracranial internal carotid, the contralateral carotid to the anterior cerebral artery and across the circle of Willis through the anterior communicating artery, the vertebrobasilar to the posterior cerebral artery and anterior through the posterior communicating artery, and distal interconnections between the distal middle cerebral artery with branches of the posterior and anterior cerebral arteries. The small arteries and arterioles (100 μm or less in diameter) that arise from the surface arteries and penetrate the brain parenchyma function as end arteries with few interconnections.

PHYSIOLOGY

The adult brain, which weighs about 1500 g, requires an uninterrupted supply of about 150 g of glucose and 72 L of oxygen every 24 hours. Because the brain does not store these substances, dysfunction results after only a few minutes when either the oxygen or the glucose content is reduced below critical levels. In the resting state, each cardiac contraction delivers about 70 mL of blood into the ascending aorta; 10 to 15 mL are allocated to the brain. Every minute, about 350 mL flows through each internal carotid artery and about 100 to 200 mL through the vertebrobasilar system.

To ensure constant perfusion pressure and blood flow to the brain, the major cerebral arteries have a well-developed muscular coat that allows constriction in response to increased blood pressure and dilation with hypotension. The arterioles are exquisitely sensitive to changes in Paco_2 and Pao_2 . When the partial pressure of CO_2 increases, the arterioles dilate and cerebral blood flow increases. When CO_2 tension is reduced, the arterioles constrict and blood flow is reduced. Changes in the partial pressure of O_2 have the opposite effect. Focal cerebral activity, such as occurs when moving a limb, is accompanied by accelerated metabolism in the appropriate region, which is accommodated by an increase in the local blood flow. In patients with cerebrovascular disease, this compensatory mechanism may be destroyed.

PATHOGENESIS AND CLASSIFICATION

Brain Infarction

When blood supply is interrupted for 30 seconds, brain metabolism is altered. After 1 minute, neuronal function may cease. After 5 minutes, anoxia initiates a chain of events that may result in cerebral infarction; however, if oxygenated blood flow is restored quickly enough, the damage may be reversible. The following steps occur in the evolution of an infarct: (a) local vasodilatation and (b) stasis of the blood column with segmentation of the red cells are followed by (c) edema and (d) necrosis of brain tissue ([Fig. 35.3](#)).

FIG. 35.3. Acute infarct, right middle cerebral artery distribution. Noncontrast axial computed tomography shows right frontal and temporal hypodensity, including cortex and edema producing ventricular effacement and midline shift. Right anterior and posterior cerebral artery territories are spared. Similar appearance could result from occlusion of right internal carotid artery with competent circle of Willis. (Courtesy of Drs. J.A. Bello and S.K. Hilal.)

Exciting research into the cellular consequences of ischemia have led to the elucidation of the ischemic cascade. A chain of events at the neuronal level leads to cellular dysfunction and death starting with the failure of the Na/K pump, the depolarization of the neuronal membrane, the release of excitatory neurotransmitters, and the opening of calcium channels. The influx of calcium is at the root of further neuronal injury with damage to organelles and further destabilization of neuronal metabolism and normal function. Calcium may enter the neuron through various voltage-sensitive and receptor-mediated channels (i.e., the *N*-methyl-d-aspartate receptor). Excitatory neurotransmitters such as glutamate and glycine can lead to the further influx of calcium through these channels. These events can lead to delayed neuronal death and are the main target of various neuroprotective strategies. The ischemic penumbra has been defined as the region of brain surrounding the core of an infarct in which neuronal function is deranged but potentially salvageable.

Persistently reduced perfusion and the consequences of the ischemic cascade can lead to extension of the core of the infarct to encompass the ischemic penumbra. If the interruption to blood flow is sufficiently prolonged and infarction results, the brain tissue first softens and then liquefies; a cavity finally forms when the debris is removed by the phagocytic microglia. In attempts to fill the defect, astroglia in the surrounding brain proliferate and invade the softened area, and new capillaries are formed.

Although most infarcts are bland, a hemorrhagic infarct occasionally is caused by local hemorrhage into the necrotic tissue, which may be petechial or confluent. Hemorrhagic infarct may occur when the occluding clot or embolus breaks up and migrates, thereby restoring flow through the infarcted area. More widespread use of magnetic resonance imaging (MRI) has shown that petechial hemorrhagic infarction is more frequent than originally suspected and is related to size of the infarct and elevation of blood pressure ([Fig. 35.4](#)).

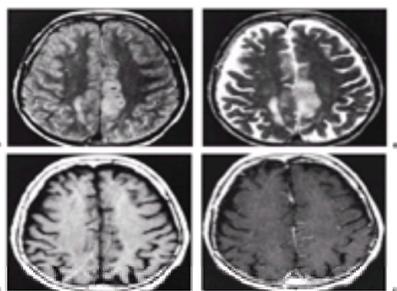

FIG. 35.4. Acute cortical infarction. **A and B:** Proton-density and T2-weighted axial magnetic resonance scans show increased signal intensity within the medial cortex of left frontal and parietal lobes. Note swelling of gray matter and prominence of blood vessels within this lesion. **C and D:** T1-weighted axial magnetic resonance scans before and after gadolinium administration demonstrate several linear foci of contrast enhancement within the area of infarction in the left frontal and parietal lobes, most consistent with enhancing arterial branches. Contrast enhancement of arterial branches is consistent with static blood flow within the infarct and generally is seen only within the first few hours to 5 days after the onset of acute infarction. (Courtesy of Dr. S. Chan.)

Infarction may be confined to a single vascular territory when the occlusion involves a small penetrant end-artery or distal intracranial branch. If the occlusion is more proximal in the arterial tree, ischemia may be more widespread and may involve more than one vascular territory or border zone ischemia may result with limited infarction in the distal fields of the vascular supply. Intracranial proximal occlusions may result in both penetrant artery ischemia and coexisting surface branch territory infarction.

Multiple mechanisms may lead to brain ischemia. Hemodynamic infarction originates as a result of an impediment to normal perfusion that usually is caused by a severe arterial stenosis or occlusion caused by atherosclerosis and coexisting thrombosis. Embolism occurs when a particle of thrombus originating from a more proximal source (arterial, cardiac, or transcerebral) travels through the vascular system and leads to an arterial occlusion. Small-vessel disease occurs when lipohyalinosis or local atherosclerotic disease leads to an occlusion of a penetrant artery. Less frequent conditions that lead to reductions in cerebral perfusion and result in infarction are arterial dissection, primary or secondary vasculitis (e.g., meningitis caused by tuberculosis or syphilis), hypercoagulable states, vasospasm, systemic hypotension, hyperviscosity (as in polycythemia, dysproteinemia, or thrombocytosis), moyamoya disease, fibromuscular dysplasia, extrinsic compression of the major arteries by tumor, and occlusion of the veins that drain the brain. The four most frequent subtypes of cerebral infarction are atherosclerotic, cardioembolic, small vessel (lacunar), and cryptogenic.

Atherosclerotic Infarction

Atherosclerotic plaque at a bifurcation or curve in one of the larger vessels leads to progressive stenosis with the final large artery occlusion caused by thrombosis of the narrowed lumen ([Fig. 35.5](#)). Atherosclerotic plaques may develop at any point along the carotid artery and the vertebrobasilar system, but the most common sites are the bifurcation of the common carotid artery into the external and internal carotid arteries, the origins of the middle and anterior cerebral arteries, and the origins of the vertebral from the subclavian arteries ([Table 35.1](#)).

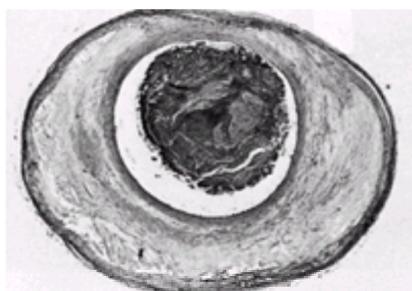

FIG. 35.5. Carotid artery in cross-section. Note atherosclerotic changes and intraluminal thrombus.

TABLE 35.1. ANGIOGRAPHIC FINDINGS AMONG 79 PATIENTS WITH ATHEROSCLEROTIC INFARCTION IN THE NINDS STROKE DATA BANK^a

Ischemia is attributed to perfusion failure distal to the site of severe stenosis or occlusion of the major vessel. The site of infarction depends on the collateral flow but is usually in the distal fields or border zones. Specifying the degree of stenosis that will lead to perfusion difficulty depends on multiple factors and often is not defined easily. Classification schemes have relied on stenosis greater than 70% to 80% as more predictive of impending hemodynamic compromise.

An atherosclerotic stenosis or occlusion can also lead to a cerebral infarction through an embolic mechanism. In this case, emboli arising from the proximally situated atheromatous lesions occlude otherwise healthy branches located more distal in the arterial tree ([Fig. 35.6](#)). Embolic fragments may arise from extracranial arteries affected by stenosis or ulcer, stenosis of any major cerebral artery stem, the stump of the occluded internal carotid artery, and even from intracranial tail of the anterograde thrombus atop an occluded carotid. The constituents of the offending embolism have earned the labels of “red” (thrombus) and “white” (platelet) clots, but it is nearly impossible to discriminate these based on clinical findings.

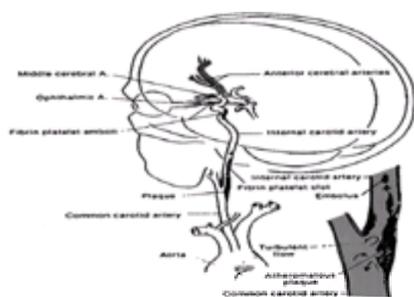

FIG. 35.6. Atheromatous plaques at the carotid bifurcation may be a source of retinal and cerebral emboli.

Cardiac Embolism

Many strokes caused by embolism originate from a cardiac source of thrombus. A small particle of thrombus breaks off from the source and is carried through the bloodstream until it lodges in an artery too small to allow it to pass, usually a distal intracranial branch. Besides thrombus, other types of particles may embolize, such as neoplasm, fat, air, or other foreign substances. Air embolism usually follows injuries or surgical procedures involving the lungs, the dural sinuses, or jugular veins. It also may be caused by the release of nitrogen bubbles into the general circulation after a rapid reduction in barometric pressure. Fat embolism is rare and almost always arises from a bone fracture. Most emboli are sterile, but some may contain bacteria if emboli arise secondary to subacute or acute bacterial endocarditis. The most common sources of cardiac embolism include valvular heart disease (mitral stenosis, mitral regurgitation, rheumatic heart disease); intracardiac thrombus, particularly along the left ventricular wall (mural thrombus) after anterior myocardial infarction or in the left atrial appendage in patients with atrial fibrillation; ventricular or septal aneurysm; and cardiomyopathies leading to stagnation of blood flow and an increased propensity for the formation of intracardiac thrombus ([Table 35.2](#)). A “paradoxical” embolus occurs when a thrombus crosses from the venous circulation to the left side of the heart, most often through a patent foramen ovale. Other possible causes of cerebral embolism are atrial myxoma, marantic endocarditis, and severe prolapse of the mitral valve.

Abnormalities	n	Percent
History		
Cardiac disease	182	74
Atrial fibrillation	98	40
Abnormal first electrocardiogram	224	91

TABLE 35.2. FREQUENCY OF CARDIAC DISEASE AMONG 246 PATIENTS WITH CARDIOEMBOLIC INFARCTION IN THE NINDS STROKE DATA BANK

Embolism is inferred when the brain image demonstrates an infarction confined to the cerebral surface territory of a single branch, combinations of infarcts involving branches of different divisions of major cerebral arteries, or hemorrhagic infarction. The difficult problem in arriving at a diagnosis of embolism is the identification of the occluding particle and the source. Mural thrombi and platelet aggregates are remarkably evanescent, as has been inferred by findings on angiography. Embolic fragments are found in more than 75% of patients who undergo angiography within 48 hours of onset of the stroke and are then gone when angiogram is repeated later. Embolism is demonstrated in only 11% of clinically similar cases when angiogram is delayed beyond 48 hours from clinical onset of the stroke. Persistence of embolic occlusion is the exception rather than the rule. Embolic obstruction of an arterial lumen is cleared most commonly by recanalization and fibrinolysis. During this process, the lumen may appear “stenotic.” The evanescent quality of emboli may explain the wide variation in the frequency with which this subtype is diagnosed in retrospective or prospective studies of stroke. More recently, the improved sensitivities of cerebral and cardiac imaging have led to better detection of sources of thrombus.

Small Vessel Lacunar Infarction

These strokes have distinctive clinical syndromes with a small zone of ischemia confined to the territory of a single vessel. They are understood to reflect arterial disease of the vessels penetrating the brain to supply the internal capsule, basal ganglia, thalamus, corona radiata, and paramedian regions of the brainstem ([Fig. 35.7](#)). Disagreements abound about the pathogenesis of lacunar infarcts; some authors favor the use of the term “lacune” to describe size and location without indicating a specific pathology. Only a handful of such infarcts have been studied pathologically by serial section, and only a few studies have documented a tiny focus of microatheroma or lipohyalinosis stenosing one of the deep penetrating arteries. The arterial damage is usually the result of long-standing hypertension or diabetes mellitus. Rare causes include stenosis of the middle cerebral artery stem or microembolization to penetrant arterial territories. Most radiologically defined

small deep infarcts do not have significant large-artery atherosclerosis, lack even a potential cardiac source of embolism, and occur in vascular territories less likely to be occluded by emboli.

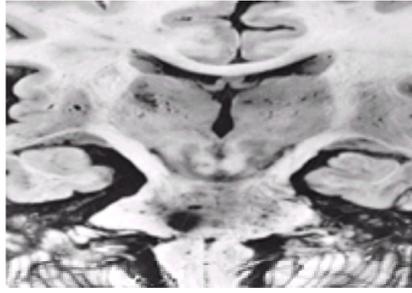

FIG. 35.7. Longitudinal cut through basal ganglia, midbrain, pons, and brainstem shows multiple lacunar infarctions and a small pontine hemorrhage.

Many lacunar strokes are diagnosed by clinical characteristics alone. Clinical syndromes include pure motor hemiparesis, pure sensory syndrome, clumsy hand dysarthria, ataxic hemiparesis, and sensorimotor stroke ([Table 35.3](#)). When brain imaging is positive, a strategically placed small deep infarct is usually found. Because the vascular lesion lies in vessels some 200 to 400 μm in diameter, cerebral angiography understandably is normal. Incidental large vessel disease may be found in some series, but whether it is etiologically related to the site of infarction is often unclear.

Syndrome	n	Percent
Pure motor hemiparesis	181	57
Sensorimotor	63	20
Ataxic hemiparesis	33	10
Pure sensory	21	7
Dysarthria—clumsy hand	18	6

TABLE 35.3. FREQUENCY OF LACUNAR SYNDROMES AMONG 316 LACUNAR INFARCTS IN THE NINDS STROKE DATA BANK

Cryptogenic Infarction

Despite efforts to arrive at a diagnosis, the cause of infarction in a discouragingly large number of cases remains undetermined. Some cases may be unexplained because no appropriate laboratory studies are performed, whereas others remain undetermined because of improper timing of the appropriate laboratory studies. The most frequent circumstances, however, are when normal or ambiguous findings are reached despite appropriate laboratory studies performed at the appropriate time. Results from the Stroke Data Bank indicated that large artery atherosclerotic occlusive disease was a less frequent cause of stroke, that small vessel or lacunar and cardioembolic infarction were relatively frequent, and that the cause for most cases of infarction could not be classified into these traditional diagnostic categories. This conclusion forced the creation of a separate diagnostic category for cases whose mechanisms of infarction remained unproven, known as “infarct of undetermined cause” or “cryptogenic infarction.”

Cases categorized as cryptogenic infarction have no bruit or TIA ipsilateral to the hemisphere affected by stroke, no obvious history suggestive of cardiac embolism, and usually do not present with a lacunar syndrome. Computed tomography (CT) or magnetic resonance imaging performed within 7 days may be normal, may show an infarct limited to a surface branch territory, or may show a large zone of infarction affecting regions larger than that accounted for by a single penetrant arterial territory. Noninvasive vascular imaging fails to demonstrate an underlying large vessel occlusion or stenosis. No cardiac source of embolism is uncovered by echocardiography, electrocardiography, or Holter monitor. If an angiogram is performed, the study may be normal, may show a distal branch occlusion, or may show occlusion of a major cerebral artery stem or of the top of the basilar. Because these latter occlusions can arise from embolus or thrombosis of an atherosclerotic vessel, their demonstration does not solve the question of mechanism.

Many of these patients present with a hemispherical syndrome, a surface infarction revealed by CT or magnetic resonance imaging, and a corresponding branch occlusion documented by angiography or normal angiogram. This constellation of findings has been considered suggestive of embolism. Ample evidence exists for many occult sources of emboli; the difficulty is in proving their existence and their role in the first or succeeding ischemic strokes. Emerging technologies have led to the suggestion that some cryptogenic infarcts may be explained by hematologic disorders causing hypercoagulable states from protein C, free protein S, lupus anticoagulant, or anticardiolipin antibody abnormalities. Others have implicated paradoxical emboli through a patent foramen ovale and aortic arch atherosclerosis. Rather than reclassifying these cases into embolism as the inferred mechanism, such cases should be labeled as “cryptogenic” until the mechanism, source, and determinants of these unexplained infarcts are clarified.

Intracranial Hemorrhage

Hemorrhage results from rupture of a vessel anywhere within the cranial cavity. Intracranial hemorrhages are classified according to location (extradural, subdural, subarachnoid, intracerebral, intraventricular), according to the nature of the ruptured vessel or vessels (arterial, capillary, venous), or according to cause (primary, secondary). Trauma often is involved in the generation of extradural hematoma from laceration of the middle meningeal artery or vein and subdural hematomas from traumatic rupture of veins that traverse the subdural space.

Intracerebral Hemorrhage

Intracerebral hemorrhage is characterized by bleeding into the substance of the brain, usually from a small penetrating artery. Hypertension has been implicated as the cause of a weakening in the walls of arterioles and the formation of microaneurysms (Charcot-Bouchard). Among elderly nonhypertensive patients with recurrent lobar hemorrhages, amyloid angiopathy has been implicated as an important cause. Other causes include arteriovenous malformations, aneurysms, moyamoya disease, bleeding disorders or anticoagulation, trauma, tumors, cavernous angiomas, and illicit drug abuse. In blood dyscrasias (e.g., acute leukemia, aplastic anemia, polycythemia, thrombocytopenic purpura, scurvy), the hemorrhages may be multiple and of varied size.

The arterial blood ruptures under pressure and destroys or displaces brain tissue. If the hemorrhage is large, the ruptured vessel is often impossible to find at autopsy. The most common sites are the putamen, caudate, pons, cerebellum, thalamus, or deep white matter ([Table 35.4](#)). Basal ganglia hemorrhages often extend to involve the internal capsule and sometimes rupture into the lateral ventricle and spread through the ventricular system into the subarachnoid space ([Fig. 35.8](#)). Intraventricular extension increases the likelihood of a fatal outcome. Bleeding into one lobe of the cerebral hemisphere or cerebellum usually remains confined within brain parenchyma. An inferior cerebellar hemorrhage is a neurologic emergency that needs to be diagnosed promptly, because early surgical evacuation of those greater than 3 cm can prevent tonsillar herniation and apnea.

TABLE 35.4. DISTRIBUTION BY LOCATION OF CT-DIAGNOSED PRIMARY INTRACEREBRAL HEMORRHAGE AMONG 203 PATIENTS IN THE NINDS STROKE DATA BANK

If the patient survives an intracerebral hemorrhage, blood and necrotic brain tissue are removed by phagocytes. The destroyed brain tissue is partially replaced by connective tissue, glia, and newly formed blood vessels, thus leaving a shrunken fluid-filled cavity. Less frequently, the blood clot is treated as a foreign body, calcifies, and is surrounded by a thick glial membrane.

The clinical picture is dictated by the location and size of the hematoma. It is characterized by headache, vomiting, and the evolution of focal motor or sensory signs over minutes to hours. Consciousness is sometimes impaired at the start and often becomes a prominent feature in the first 24 to 48 hours among the moderate and large hematomas. Patients with intracerebral hemorrhage are often younger and more frequently have been men in some series. The diagnosis and localization are established easily with CT, which shows the high density of acute blood.

Subarachnoid Hemorrhage

Subarachnoid hemorrhage occurs when the blood is localized to the surrounding membranes and cerebrospinal fluid. It is most frequently caused by leakage of blood from a cerebral aneurysm. The combination of congenital and acquired factors leads to a degeneration of the arterial wall and the release of blood under arterial pressures into the subarachnoid space and cerebrospinal fluid. Aneurysms are distributed at different sites throughout the base of the brain, particularly at the origin or bifurcations of arteries at the circle of Willis. Other secondary causes that may lead to subarachnoid hemorrhage include arteriovenous malformations, bleeding disorders or anticoagulation, trauma, amyloid angiopathy, or central sinus thrombosis. Signs and symptoms include the abrupt onset of severe headache (“the worst headache of your life”), vomiting, altered consciousness, and sometimes coma; these characteristics often occur in the absence of focal localizing signs.

Subarachnoid hemorrhage afflicts younger patients and women more often than men. Hypertension, oral contraceptive use, and cigarette smoking are some of the known factors associated with this type of stroke. Fatalities are high, ranging from 30% to 70%, and depend on the severity of the initial presentation. Among those who survive, early rebleeding and delayed ischemic neurologic deficits from vasospasm can cause serious morbidity.

Frequency of Stroke Subtypes

Overall, ischemic stroke is three to four times as frequent as hemorrhagic stroke, accounting for 70% to 80% of all strokes. Intracerebral hemorrhage usually accounts for 10% to 30% of the cases, depending on the geographic origin of the patients, with greater relative frequencies reported in Chinese and Japanese series.

Frequency of subarachnoid hemorrhage is usually one-third to one-half that of intracerebral hemorrhage. Frequency of infarct subtypes depend on the sample from which cases are drawn (hospital or population based), the geographic region of the study, and the design of investigator-driven diagnostic algorithms.

Cardioembolism ranges from 15% to 30% of the cases, atherosclerotic infarction varies from 14% to 40%, and lacunar infarcts account for 15% to 30%. Stroke from other determined causes, such as arteritis or dissection, usually accounts for a small percentage (less than 5%) of the cases. Infarcts of undetermined cause may account for as many as 40% of ischemic infarcts (Fig. 35.9). Clinical features that are observed at stroke onset can help to distinguish cerebral infarction subtypes but are not reliable enough to lead to a definite determination of infarct subtype without confirmatory laboratory data.

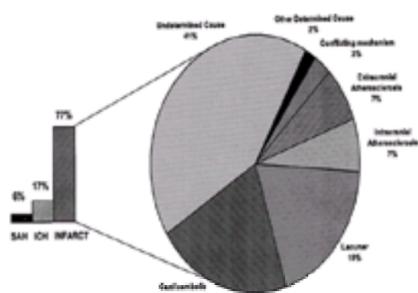

FIG. 35.9. Frequency of stroke and infarct subtypes in the Northern Manhattan Stroke Study, 1993–1997.

STROKE EPIDEMIOLOGY

Incidence, Prevalence, and Mortality

The magnitude of stroke is measured in public health terms by stroke-specific incidence, prevalence, and mortality. Stroke incidence is defined by the number of first cases of stroke over a defined time interval in a defined population, whereas stroke prevalence measures the total number of cases, new and old, at a particular time also in a defined population. Both indices depend on the accurate and complete enumeration of cases and adequate knowledge of the underlying population at risk.

Stroke incidence can be viewed as the sum of hospitalized, sudden fatal, and nonhospitalized stroke. Therefore, stroke incidence estimations depend on whether the data are gathered clinically, by CT, or at autopsy and whether the study is hospital or population based. The American Heart Association estimates that in the United States, almost 4 million stroke survivors exist (prevalence) and approximately 600,000 new or recurrent strokes occur per year. Overall, age-adjusted incidence rates range between 100 and 300 per 100,000 population per year and depend on the study methodology, country of origin, and population demographics.

Mortality data are readily available but may underestimate the magnitude of stroke because not all patients with stroke die. Overall, stroke accounts for about 10% of all deaths in most industrialized countries, and most of these deaths are among persons over the age of 65. The average age-adjusted stroke mortality in the United States is 50 to 100 per 100,000 population per year, less than in Japan and China and more than in the Philippines.

Temporal Trends in Mortality

In the United States, stroke mortality has been decreasing since the early 1900s. The rate of decline has been a constant 1% per year until 1969, when it accelerated to nearly 5% per year. The greatest decline has been in the older age groups. The reasons for this mortality trend remain a subject of controversy. Epidemiologic data support various possibilities, including declining stroke incidence, improved survival, reduction in the severity of stroke, changing diagnostic criteria, and better stroke risk factor control. Convincing evidence from National Hospital Discharge Surveys is accumulating in favor of improved survival rather than of declining incidence as the explanation for the drop in stroke mortality. Some investigators have attributed the reduction in stroke mortality to better control of hypertension, whereas others have noted that the decline began before the widespread use of antihypertensive agents and that indices of hypertension control have not correlated with stroke mortality. More recently, this decline in mortality has ceased, and some have been reporting an increase in mortality.

Determinants of Stroke

Nonmodifiable Risk Factors

Although cerebrovascular disorders may occur at any age, at any time, in either sex, in all families, and in all races, each of these nonmodifiable factors affects the incidence of stroke. The strongest determinant of stroke is age. Stroke incidence rises exponentially with age, with most strokes occurring in persons older than 65. Stroke is less common before age 40, but stroke in young adults is of growing concern because of the impact of early disability. As our population ages, the prevalence and public health impact of stroke will undoubtedly increase.

Stroke incidence is greater among men, those with a family history of stroke, and among certain race-ethnic groups (Fig. 35.10). In a hospital- and community-based cohort study of all cases of first stroke in northern Manhattan, blacks had an overall age-adjusted 1-year stroke incidence rate of 2.4 times that of whites, and Hispanics, predominately from the Dominican Republic, had an incidence rate 1.6 times that of whites. In Japan, stroke is the leading cause of death in adults, and hemorrhage is more common than atherothrombosis. The predilection of atherosclerosis for the extracranial or intracranial circulation differs by race-ethnic group. Extracranial lesions are more frequent in whites, whereas intracranial lesions are more common in blacks, Hispanics, and Asians. The reasons for these differences have yet to be explained adequately.

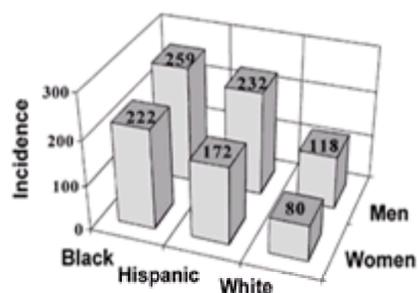

FIG. 35.10. Average age-adjusted incidence rates of stroke (per 100,000 population) among persons aged 20 years in northern Manhattan in white, black, and Hispanic women. (Adapted from Sacco RC, Boden-Abdalla B, et al., 1998.)

Modifiable Risk Factors

Nothing is accidental about stroke, as implied by the misnomer “cerebral vascular accident.” Instead, stroke is usually the result of predisposing conditions that originated years before the ictus. Epidemiologic investigations, such as prospective cohort and case-control studies, are continuing to identify numerous stroke risk factors. Current modifiable components of the stroke-prone profile include hypertension, cardiac disease (particularly atrial fibrillation), diabetes, hypercholesterolemia, physical inactivity, cigarette use, alcohol abuse, asymptomatic carotid stenosis, and a history of TIAs (Table 35.5).

Risk factors	Modification
Hypertension	Antihypertensives, diet
Heart disease	Antiplatelets
Atrial fibrillation	Anticoagulants, antiarrhythmics
Diabetes mellitus	Glucose control
Hypercholesterolemia	Lipid-lowering medication, diet
Physical inactivity	Routine exercise
Smoking	Cessation
Heavy alcohol use	Quantity reduction
Asymptomatic carotid stenosis	Antiplatelets, endarterectomy
Transient ischemic attack	Antiplatelets, endarterectomy, anticoagulants

TABLE 35.5. MODIFIABLE RISK FACTORS THAT CAN INCREASE THE PROBABILITY OF STROKE

After age, hypertension is the most powerful stroke risk factor. It is prevalent in the population of the United States in both men and women and is of even greater significance in blacks. The risk of stroke rises proportionately with increasing blood pressure. In Framingham, the relative risk of stroke for a 10-mm Hg increase in systolic blood pressure was 1.9 for men and 1.7 for women after controlling for other known stroke risk factors. Elevated systolic or diastolic blood pressure (or both) increases stroke risk by accelerating the progression of atherosclerosis and predisposing to small vessel disease.

Cardiac disease clearly has been associated with an increased risk of ischemic stroke, particularly atrial fibrillation, valvular heart disease, myocardial infarction, coronary artery disease, congestive heart failure, electrocardiographic evidence of left ventricular hypertrophy, and perhaps mitral valve prolapse. Chronic atrial fibrillation affects more than 1 million Americans and becomes more frequent with age. In the Framingham Study, atrial fibrillation was a strong predictor of stroke, with a nearly fivefold increased risk of stroke. In those with coronary heart disease or cardiac failure, atrial fibrillation doubled the stroke risk in men and tripled the risk in women. With coexisting valvular disease, atrial fibrillation had an even greater impact on the relative risk of stroke. Left ventricular dysfunction and left atrial size determined by echocardiography were also predictors of increased thromboembolic risk.

Stroke risk nearly doubles in those with antecedent coronary artery disease and nearly quadruples in subjects with cardiac failure. Even after adjusting for the presence of other risk factors, left ventricular hypertrophy increased the risk of stroke by 2.3 in both men and women, and mitral annular calcification was associated

with a relative risk of stroke of 2.1. Improved cardiac imaging has led to the increased detection of such potential stroke risk factors as mitral valve prolapse, patent foramen ovale, aortic arch atherosclerotic disease, atrial septal aneurysms, valvular strands, and spontaneous echo contrast (a smokelike appearance in the left cardiac chambers visualized on transesophageal echocardiography).

Diabetes also has been associated with increased stroke risk, ranging from relative risks of 1.5 to 3.0, depending on the type and severity. The effect was found in both men and women, did not diminish with age, and was independent of hypertension.

Abnormalities of serum lipids (triglyceride, cholesterol, low-density lipoprotein, high-density lipoprotein) are regarded as risk factors, more for coronary artery disease than for cerebrovascular disease. Older meta-analyses of prospective cohort studies among somewhat younger populations have failed to verify an independent relationship between stroke and elevated cholesterol. Part of this is explained by the recognition that not all strokes are due to atherosclerosis. More recent studies have found a protective effect of high-density lipoprotein for stroke, an association between carotid plaque or intima-media thickness and lipoprotein fractions, and a significant reduction in stroke risk among persons treated with the newest class of cholesterol-reducing medicines known as the statins.

Physical inactivity is a definite predictor of cardiac death, and evidence is accumulating regarding the beneficial effects of physical activity for stroke prevention. In the Northern Manhattan Stroke Study, leisure-time physical activity was found to be significantly associated with a reduced risk of stroke among men and women, young and old, and whites, blacks, and Hispanics. Although a dose-response relationship was found, such that heavier activity and longer duration of activity were more beneficial, even light activities in which elderly individuals can engage, such as walking, conferred a significant protective effect.

Cigarette smoking has been established clearly as a biologically plausible independent determinant of stroke. After controlling for other cardiovascular risk factors, cigarette smoking has been associated with relative risks of brain infarction of 1.7. Stroke risk was greatest in heavy smokers and quickly reduced in those who quit. It was an independent determinant of carotid artery plaque thickness. The association of smoking and subarachnoid hemorrhage is particularly striking. A population-based case-control study in Kings County, Washington, demonstrated an odds ratio of 11.1 for heavy smokers (more than one pack per day) and 4.1 for light smokers (no more than one pack per day) compared with nonsmokers. Overall, the stroke risk attributed to cigarette smoking is greatest for subarachnoid hemorrhage; intermediate for cerebral infarction, for which atherosclerotic stroke may be the most related; and lowest for cerebral hemorrhage.

The role of alcohol as a stroke risk factor depends on stroke subtype and dose. Excess drinking has been shown to be a risk factor for both intracerebral and subarachnoid hemorrhage, whereas the relationship between alcohol and cerebral infarction has been more controversial. Results include a definite independent effect in both men and women, an effect only in men, and no effect after controlling for other confounding risk factors, such as cigarette smoking. A J-shaped relationship between alcohol and ischemic stroke has been noted in a few epidemiologic studies. The relative risk of stroke increased with heavy alcohol consumption (five or more drinks per day) and decreased with light to moderate drinking when compared with nondrinkers. In northern Manhattan, drinking up to two drinks per day was significantly protective for ischemic stroke compared with nondrinkers among old and young subjects, both men and women, and in whites, blacks and Hispanics.

Asymptomatic carotid artery disease, which includes nonstenosing plaque or carotid stenosis, has been found to be associated with an increased stroke risk, particularly among those with more than 75% stenosis. The annual stroke risk was 1.3% in those with no more than 75% stenosis and 3.3% in those with more than 75% stenosis, with an ipsilateral stroke risk of 2.5%. The combined TIA and stroke risk was 10.5% per year in those with more than 75% carotid stenosis. Among persons with asymptomatic carotid artery disease, the occurrence of symptoms may depend on the severity and progression of the stenosis, the adequacy of collateral circulation, the character of the atherosclerotic plaque, and the propensity to form thrombus at the site of the stenosis.

TIA's are a strong indicator of subsequent stroke, with annual stroke risks ranging from 1% to 15%. The first year after a TIA seems to have the greatest stroke risk. Amaurosis fugax or transient monocular blindness has a better outcome than hemispheric ischemic attacks. TIA's, however, precede cerebral infarction in fewer than 20% of patients. The stroke risk after TIA probably depends on the presence and severity of underlying atherosclerotic disease, vascular distribution, adequacy of collateral perfusion, and distribution of confounding risk factors. These variables must be considered before comparing different studies or extrapolating results with the individual patient.

Potential Risk Factors

Other potential stroke risk factors identified by some studies need to be confirmed and clarified in further epidemiologic investigations. Migraine, oral contraceptive use, drug abuse, and snoring have been associated with a higher stroke risk. Various laboratory abnormalities, often reflecting an underlying metabolic or hematologic disturbance, have been associated with stroke and identified as possible stroke precursors. These include hematocrit, polycythemia, sickle cell anemia, white blood count, fibrinogen, hyperuricemia, hyperhomocysteinemia, protein C and free protein S deficiencies, lupus anticoagulant, and anticardiolipin antibodies. Some are clear stroke risk factors, whereas others require further epidemiologic investigations.

Outcome

The immediate period after an ischemic stroke carries the greatest risk of death, with fatality rates ranging from 8% to 20% in the first 30 days. Death is more likely the result of cardiopulmonary complications rather than of brain death from transtentorial herniation. Case fatality rates are worse for hemorrhagic strokes, ranging from 30% to 80% for intracerebral and 20% to 50% for subarachnoid hemorrhage. Characteristics that can be determined at the onset of stroke and used by the clinician to predict early mortality include impaired consciousness, severity of the initial clinical syndrome, hyperglycemia, and age.

Relatively little is known about the predictors of late stroke outcome. Survivors of the initial ictus continue to have a three to five times increased risk of death compared with the age-matched general population. Annual aggregate estimates of death have been 5% for minor stroke and 8% for major stroke. Survival is influenced by age, hypertension, cardiac disease (myocardial infarction, atrial fibrillation, congestive heart failure), and diabetes. Moreover, patients with lacunar infarcts appear to have a better long-term survival than do those with the other infarct subtypes.

Recurrent stroke is frequent and is responsible for major stroke morbidity and mortality. The immediate period after a stroke carries the greatest risk for early recurrence; rates range from 3% to 10% during the first 30 days. Early stroke recurrence is no trivial matter because of significant worsening of neurologic disability, an increased risk of mortality, and clearly a longer hospital stay. Thirty-day recurrence risks varied by infarct subtypes; the greatest rates were found in patients with atherosclerotic infarction and the lowest rates in patients with lacunes. After the early phase, stroke recurrence continues to threaten the quality of life after stroke. Long-term stroke recurrence rates range in different studies from 4% to 14% per year, with aggregate annual estimates of 6% for minor stroke and 9% for major stroke (Fig. 35.11).

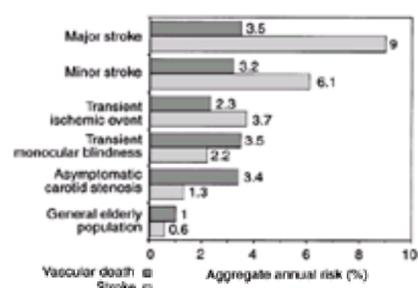

FIG. 35.11. Aggregate estimates of annual vascular events in various subgroups. (Adapted from Wilterdink et al. 1992)

Universal agreement has not been reached on the predictors of stroke recurrence. Although age is an important predictor of survival after stroke, both young and old are at risk for stroke recurrence. Some studies have found no effect of hypertension and cardiac disease, whereas others have suggested that these factors increased recurrence after stroke. Valvular disease, congestive heart failure, and atrial fibrillation have been found to be determinants of recurrent stroke. In northern

Manhattan, hyperglycemia and ethanol abuse, in addition to hypertension, were identified as predictors of stroke recurrence within 5 years. Further studies are required to clarify the predictors of stroke recurrences, which will have increasing public health significance and account for a greater share of the annual cost of stroke-related health care as our population ages and the decline of stroke mortality continues.

CHAPTER 36. EXAMINATION OF THE PATIENT WITH CEREBROVASCULAR DISEASE

RANDOLPH S. MARSHALL

[General Examination](#)
[Neurologic Evaluation](#)
[Suggested Readings](#)

The goal of the examination of a patient suspected of having a stroke is to gain immediate information about the probable size, location, and etiology of the stroke. Successful treatment depends on starting within a few hours after the onset. Brain imaging has advanced to allow detection of ischemia within minutes to hours after symptoms begin; imaging is necessary to identify hemorrhage before treatment is considered. Nevertheless, the examining physician has the responsibility to identify the symptoms and signs that guide subsequent therapy. For patients who arrive too late, beyond the time window for acute treatment, the neurologic examination is the first step in the diagnostic workup to establish stroke etiology and to start proper treatment aimed at preventing recurrence of stroke.

GENERAL EXAMINATION

Evaluation of the patient with a suspected stroke of large size must first address the level of consciousness and cardiopulmonary status. Irregular or labored breathing and a decreased level of consciousness, particularly if accompanied by gaze deviation, hemiparesis, or unequal pupils, may indicate the need for immediate intubation to treat impending herniation from massive infarction. Reduced alertness is a sign of either extensive hemispherical injury or involvement of the brainstem reticular activating system, which could result from brainstem infarction or from compression on the brainstem by the herniating uncus of the temporal lobe.

The terms “lethargic” and “stuporous” are often used to describe levels of decreasing consciousness, but it is most useful to describe alertness in terms of the minimal stimulus required for a given response (e.g., “opens eyes to voice” or “semipurposeful withdrawal to moderate noxious stimulus”). Subtler impairment of attention and concentration is tested by asking the patient to count backward from 20 to 1 or say the months of the year backward. The level of alertness may fluctuate after injury to the thalamus, often a hemorrhage. Coexisting metabolic derangement such as drug toxicity or hyperglycemia must be ruled out with appropriate laboratory tests. Papilledema is an additional sign of increased intracranial pressure. Cheyne-Stokes respirations with normal level of consciousness may be associated with a smaller territory infarction that involves the insula. Cardiac conduction defects, arrhythmias, subendothelial myocardial infarction, and neurogenic pulmonary edema may occur as a consequence of subarachnoid hemorrhage or large territory infarction, presumably from centrally mediated increase in sympathetic neurotransmitter release. The blood pressure rises acutely in 70% to 80% of stroke patients as a consequence of the infarction or hemorrhage and then returns to baseline spontaneously over the course of a few days. Except for malignant hypertension with encephalopathy or hypertensive cerebral hematoma identified on brain computed tomography, blood pressure is not treated acutely. Nuchal rigidity is often present in subarachnoid hemorrhage. Fever may rarely be caused by brainstem infarction or subarachnoid hemorrhage. A systemic etiology must be sought and treated, however, because fever can exacerbate ischemic brain injury.

Beyond the examination required for emergency management of acute stroke, the general examination should focus on the cardiovascular system to seek a likely stroke etiology. Examination of the neck includes auscultation for carotid bruits, which result from turbulent flow in an artery narrowed by an atherosclerotic plaque. Auscultation of bruits may be misleading if the sound arises from stenosis of the unimportant external carotid artery or if the degree of stenosis in the internal carotid artery is great enough to dampen flow velocity below that which produces an audible bruit. Doppler ultrasound or magnetic resonance angiogram of the neck is needed if carotid stenosis is suspected. Fundoscopy can show retinal arterial narrowing, subhyloid hemorrhages, or cotton wool spots—systemic signs of hypertension or diabetes.

The presence of murmurs or arrhythmia on cardiac examination suggests valvular disease or atrial fibrillation, both independent risk factors and indications for anticoagulation therapy to prevent recurrence of stroke. The presence of fever with a cardiac murmur requires blood culture to rule out bacterial endocarditis. Auscultation of the lungs is important as a means of identifying signs of aspiration pneumonia or pulmonary edema caused by congestive heart failure.

NEUROLOGIC EVALUATION

The neurologic examination can provide valuable clues to the size, location, and etiology of the stroke. A few syndromes are predictive of specific stroke etiologies. For example, Wernicke aphasia, homonymous hemianopia, and the “top-of-the-basilar” syndrome of cortical blindness, agitation, and amnesia are nearly always caused by embolism from a proximal arterial or cardiac source. The Wallenberg syndrome, due to infarction of the dorsolateral medulla, is typically caused by thrombosis of the vertebral artery. The “lacunar syndromes” (see below) nearly always result from lipohyalinosis and fibrinoid necrosis of small penetrating arterioles arising from the middle cerebral artery stems, the basilar artery, or the first portion of the posterior cerebral arteries. The severity of the clinical syndrome at onset is highly correlated with the ultimate functional outcome. Level of alertness, ocular motility, motor power, and higher cerebral function are the keys to initial assessment. The most common sign of large stroke is the combination of gaze deviation, hemiparesis, and altered mentation. Hyperhidrosis, or excessive sweating, sometimes unilateral, may also occur in brainstem hemorrhage or large hemisphere stroke. In a comatose patient, asymmetry of tendon reflexes supports a diagnosis of unilateral brain injury when motor and sensory testing are not possible. Hypotonia may occur early after stroke, whereas tone often increases only after several days.

Even if fully alert, patients with gaze deviation and hemiparesis who are within the first several hours after stroke onset are at high risk for profound clinical worsening because of an edema-related mass effect that may peak as late as 3 to 5 days after stroke. Gaze palsies often occur with infarction involving the dorsolateral frontal lobes, producing gaze deviation to the opposite side of the hemiparesis. Infarction of the lateral pons, on the other hand, produces hemiparesis on the same side as the direction of forced gaze. Other ocular dysmotility syndromes, including internuclear ophthalmoplegia, vertical gaze palsies, and nystagmus, may also occur with smaller infarcts in the brainstem. Visual fields should be tested by asking the patient to count fingers or identify a moving finger in each of four visual quadrants. Homonymous hemianopia may be the only sign of a large posterior cerebral artery territory infarction. An upper or lower homonymous quadrantanopia is produced by infarction involving the optic radiations hugging the lateral ventricular wall in the temporal or parietal lobe, respectively. A sectoranopia may be produced by injury to the lateral geniculate body of the thalamus due to anterior choroidal artery embolism.

Cortical involvement is suggested when aphasia or hemineglect are present. As a sign of dominant hemisphere injury, aphasia may involve abnormal naming, fluency, comprehension, repetition, reading, or writing. Dysfluency predominates with frontal lobe injury, whereas comprehension deficits predominate with posterior temporal and parietal injury. Severe Wernicke aphasia is characterized by poor auditory and reading comprehension and fluent speech littered with paraphasic errors; the syndrome may be misdiagnosed as delirium in the emergency room. Hemineglect, produced most often by nondominant parietal or frontal lobe injury, can be identified by unilateral extinction of visual or tactile stimuli when bilateral stimuli are presented. Rightward deviation on a line bisection test and failure to identify stimuli on the left side of an array of stimuli are also reliable signs of left hemineglect. Short-term verbal memory may be acutely affected by stroke when one or both anteromedial thalami or medial temporal lobes are involved. Short-term memory is easily tested by asking the patient to recall three objects after a 5-minute delay. Long-term memory impairment may appear as disorientation or dementia in a patient with multiple prior strokes in both hemispheres.

Unilateral weakness is typical of stroke. A complete characterization of the motor loss is important because the distribution and time course of weakness will differ by stroke location and etiology. Proximal and distal upper and lower limbs should be assessed independently on a five-point scale of power. Subtle weakness may be apparent only by the presence of a flattened nasolabial fold or widened palpebral fissure on one side of the face or a unilateral pronator drift when the patient is asked to hold the arms outstretched, palms up. Slowed or clumsy fine movements of one hand or ataxic dysmetria on finger-nose-finger may follow a stroke involving either the contralateral corticospinal tract or the ipsilateral cerebellum or cerebellar connections to the brainstem.

Weakness affecting the face, arm, and leg equally in a fully awake patient implies a small infarct in a deep brain region such as the posterior limb of the internal capsule, where the fibers of the corticospinal tract converge into a small anatomic area. This “pure motor hemiparesis” is one of four classic lacunar syndromes caused by small deep infarcts in the capsule, basal ganglia, thalamus, or pons. Hemispheric sensory loss is the syndrome associated with a thalamic lacune. “Clumsy hand dysarthria” or “ataxic hemiparesis” may result from lacunes in the corticospinal tract at any level from the corona radiata to the pons. “Fractionated hemiparesis,” for example facio-linguo-brachial paresis with little or no leg weakness, suggests cortical involvement of the perisylvian region due to embolic occlusion of a branch of the middle cerebral artery. An even smaller middle cerebral artery branch occlusion may produce isolated hand weakness, mimicking an ulnar or median neuropathy. Weakness that affects the leg suggests a paramedian infarction due to embolic occlusion of the anterior cerebral artery. Arm and face weakness from anterior cerebral artery infarction may be due to motor neglect as a consequence of injury to the paramedian supplementary motor area and cingulate gyrus.

Weakness of the proximal arm and leg sparing facial and lingual function is the most common result of "borderzone" ischemia due to hemodynamic failure from high-grade internal carotid artery stenosis. In patients with severe carotid occlusive disease, an attack of unilateral tremor or limb shaking may rarely be precipitated by standing, a sign that can be mistaken for focal seizure. Weakness due to hemodynamic failure from large vessel atherosclerosis may fluctuate before becoming a fixed hemiparesis. Stroke syndromes due to an embolic arterial occlusion are usually maximal at onset. Weakness caused by lacunar disease may sometimes have a stuttering stepwise worsening course over several days.

CHAPTER 37. TRANSIENT ISCHEMIC ATTACK

JOHN C.M. BRUST

[Suggested Readings](#)

Transient ischemic attack (TIA) describes neurologic symptoms of ischemic origin that last less than 24 hours. In fact, most attacks last only a few minutes to an hour. TIAs have more than one mechanism. When severe major carotid or vertebrobasilar stenosis is present, transient thrombosis could be operative; such TIAs tend to be brief. Attacks without severe stenosis tend to last longer and often are associated with distal branch occlusion, thereby suggesting embolism from an ulcerated plaque or a more proximal source. Some TIAs, especially vertebrobasilar, may have a hemodynamic basis, including transient hypotension and cardiac arrhythmia, and TIAs responsive to calcium-channel blockers suggest vasospasm. In the *subclavian steal syndrome*, stenosis of the left subclavian artery proximal to the origin of the vertebral artery leads to brainstem, cerebellar, or even cerebral symptoms, often during exertion and accompanied by symptoms of left arm claudication. Other TIAs may be a consequence of primary intraparenchymal vascular disease. They also have been associated with either anemia or polycythemia; such TIAs clear with correction of the underlying disorder.

Symptoms vary with the arterial territory involved. *Transient monocular blindness (amaurosis fugax)* from ischemia in the territory of the central retinal artery, a branch of the ophthalmic artery and ultimately the internal carotid artery, consists of blurring or darkening of vision, peaking within a few seconds, sometimes as if a curtain had descended, and usually clearing within minutes. In some patients, embolic particles (Hollenhorst plaques) are seen in retinal artery branches. Carotid territory TIAs that involve the brain produce varying combinations of limb weakness and sensory loss, aphasia, hemineglect, and homonymous hemianopia. Posterior circulation TIAs cause symptoms referable to the cerebrum (visual field loss or cortical blindness), brainstem (cranial nerve and long tract symptoms, sometimes crossed or bilateral), and cerebellum. Some TIAs consist of pure hemiparesis or pure hemisensory loss, thus suggesting intrinsic disease of small intraparenchymal penetrating vessels. Patients with recurrent TIAs tend to have the same type of attack each time.

The diagnosis of TIA can be difficult when symptoms are ambiguous (e.g., staggering or “drop attacks”; dizziness, light-headedness, or syncope; vertigo; fleeting diplopia; transient amnesia; atypical visual disturbance in one or both eyes such as flashes, distortions, or tunnel vision; a heavy sensation or “tiredness” in one or more limbs; and paresthesias in an area of fixed sensory loss or briefly affecting only one limb). The differential diagnosis of TIAs includes migraine, cardiac arrhythmia, seizures, hypoglycemia, and neurosis.

Although TIAs are defined in terms of their clinical reversibility and are presumed to signify ischemia too brief or incomplete to cause infarction, computed tomography and magnetic resonance imaging frequently demonstrate appropriately located infarcts. Attacks that take longer than 24 hours to clear or that leave mild residua are called reversible ischemic neurologic deficit.

The major significance of TIAs is prognostic. Such patients are at increased risk for both myocardial infarction and major stroke. “Crescendo TIAs”—two or more attacks within 24 hours—represent a medical emergency (see [Chapter 44](#)).

CHAPTER 38. CEREBRAL INFARCTION

JOHN C.M. BRUST

[Specific Vessel Occlusions](#)
[Syndromes of Infarction](#)
[Suggested Readings](#)

Ischemic syndromes of specific vessels depend not only on the site of the occlusion but on previous brain damage, collateral circulation, and variations in the region supplied by a particular artery, including aberrations in the circle of Willis (e.g., if both anterior cerebral arteries arise from a common trunk, carotid artery occlusion may cause bilateral leg weakness; if one or both posterior cerebral arteries arise from the internal carotid, occlusion of the basilar artery is less likely to cause visual symptoms). Syndromes of specific vessels do not always define the site or the nature of the occlusion (e.g., infarction in the region of the middle cerebral artery is often the result of thrombotic occlusion of the internal carotid artery; occlusion of the middle cerebral artery or its branches is usually embolic). Nonetheless, knowledge of individual artery syndromes helps the clinician to localize a lesion and to determine whether it is vascular ([Fig. 38.1](#), [Fig. 38.2](#), [Fig. 38.3](#), [Fig. 38.4](#) and [Fig. 38.5](#) and [Table 38.1](#)).

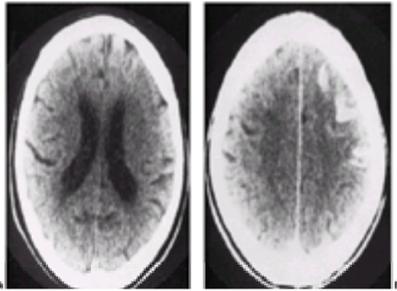

FIG. 38.1. Cerebral infarction, 1 week after stroke. **A:** Before injection of contrast material, computed tomography was normal. **B:** After injection of contrast material, there was gyral enhancement in a pattern conforming to the distribution of the middle cerebral artery. (Courtesy of Drs. S.K. Hilal and S.R. Ganti.)

FIG. 38.2. Subacute infarct, anterior and middle cerebral artery distributions. Noncontrast axial computed tomography demonstrates radiolucency in the left basal ganglia and frontal and temporal opercula extending through the cortex. Note sulcal effacement and mild shift due to recent infarction involving the left anterior and middle cerebral artery territories; the left posterior cerebral artery territory is spared. (Courtesy of Drs. J.A. Bello and S.K. Hilal.)

FIG. 38.3. Acute posterior cerebral infarct. Noncontrast axial computed tomography shows right occipital lucency, corresponding to posterior cerebral vascular distribution with mild mass effect (sulcal effacement) due to acute infarction and edema. (Courtesy of Drs. J.A. Bello and S.K. Hilal.)

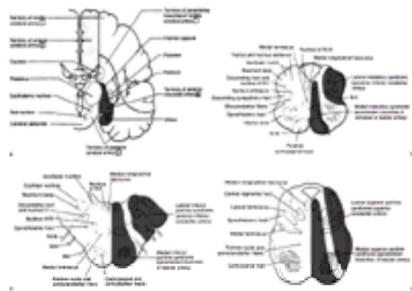

FIG. 38.4. Arterial territories of the cerebrum (**A**), of the medulla (**B**), of the lower pons (**C**), and of the upper pons (**D**).

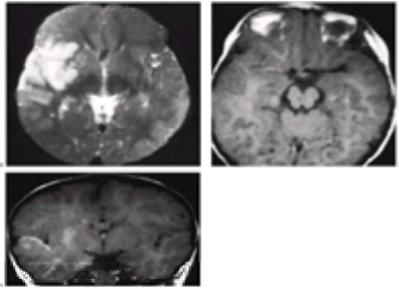

FIG. 38.5. **A:** T2-weighted axial magnetic resonance scan shows increased signal intensity throughout right frontal and temporal opercula and right putamen, most consistent with infarction. T1-weighted axial (**B**) and coronal (**C**) magnetic resonance scans show enhancement of portions of the proximal right middle cerebral artery consistent with slowing or stasis of flow in right middle cerebral artery. These findings confirm acute nature of this infarction. (Courtesy of Dr. S. Chan.)

Artery Occluded	Syndrome
Common carotid	Asymptomatic
Internal carotid	Unilateral blindness Contralateral hemiparesis and homonymous hemianopia Hemiparesis Aphasia or sensory loss and homonymous hemianopia
Middle cerebral	Homonymous hemianopia Homonymous hemianopia Aphasia or sensory loss and homonymous hemianopia
Main trunk	Homonymous hemianopia Homonymous hemianopia Aphasia or sensory loss and homonymous hemianopia
Upper division	Homonymous hemianopia and sensory loss affect face and arm more affected than leg Homonymous hemianopia and sensory loss affect face and arm more affected than leg
Lower division	Homonymous hemianopia and sensory loss affect face and arm more affected than leg Homonymous hemianopia and sensory loss affect face and arm more affected than leg
Penetrating artery	Pure motor hemiparesis
Anterior cerebral	Homonymous hemianopia and sensory loss affect leg more than arm Homonymous hemianopia and sensory loss affect leg more than arm Homonymous hemianopia and sensory loss affect leg more than arm Homonymous hemianopia and sensory loss affect leg more than arm
Posterior cerebral	Homonymous hemianopia and sensory loss affect leg more than arm Homonymous hemianopia and sensory loss affect leg more than arm Homonymous hemianopia and sensory loss affect leg more than arm Homonymous hemianopia and sensory loss affect leg more than arm

TABLE 38.1. SYNDROMES OF CEREBRAL INFARCTION

SPECIFIC VESSEL OCCLUSIONS

Middle Cerebral Artery

Infarction in the region of the middle cerebral artery causes contralateral weakness, sensory loss, homonymous hemianopia, and, depending on the hemisphere involved, either language disturbance or impaired spatial perception. If the artery's main trunk is occluded, infarction affects the cerebral convexity and deep structures, including not only the motor and sensory cortices over the cerebral convexity but also the posterior limb of the internal capsule; the face, arm, and leg are equally affected by weakness and sensory loss. If infarction spares the diencephalon after occlusion of the upper division, weakness and sensory loss are greater in the face and arm than in the leg. When infarction is limited to the region of the rolandic branch, such weakness and sensory loss may be the only signs. A small infarct or lacune in the internal capsule (from occlusion of a penetrating lenticulostriate branch of the proximal middle cerebral artery) may cause a syndrome of pure hemiparesis affecting face, arm, and leg but with no other symptoms.

With cerebral lesions, motor and sensory loss tend to be greatest distally, perhaps because the proximal limbs and the trunk are more likely to be represented in both hemispheres. Paraspinal muscles, for example, are rarely weak in unilateral cerebral disease, which also spares muscles of the forehead, pharynx, and jaw. Tongue weakness is variable. If weakness is severe, muscle tone usually decreases initially and then gradually increases in days or weeks to spasticity with hyperactive tendon reflexes. A Babinski sign is usually present from the outset. When weakness is mild or during recovery, there is more clumsiness and incoordination than loss of strength.

There is often paresis of contralateral conjugate gaze after an acute lesion in the so-called frontal gaze center anterior to the prerolandic motor cortex or in its subcortical connections; the gaze palsy usually lasts only 1 or 2 days, even when other signs remain severe. Sensory loss tends to involve discriminative and proprioceptive modalities. Pain and temperature sensation may be impaired but are seldom lost. Joint position sense, however, may be severely disturbed, causing limb ataxia or pseudoathetosis, and there may be loss of two-point discrimination, astereognosis, or failure to appreciate a touch stimulus if another is delivered simultaneously to the normal side of the body ("extinction"). Homonymous hemianopia is the result of damage to the optic radiations. If the lesion is primarily parietal, the field cut may be an inferior quadrantanopia; with temporal lesions, quadrantanopia is superior.

A lesion of the left opercular (perisylvian) cortex is likely to cause aphasia; when damage is widespread, the aphasia is global, causing muteness or nonfluent and amelodic speech and severe impairment of speech comprehension, writing, and reading abilities. Restricted damage from branch occlusions can cause an aphasic syndrome. Frontal opercular lesions tend to cause Broca aphasia, with impaired speaking and writing ability but with relative preservation of comprehension. (The relative contributions of cortical and white matter damage to this type of aphasia are controversial.) With posterior periopercular lesions, fluency and prosody are preserved, but paraphasia can reduce speech output to jargon; there may be impairment of speech comprehension and naming, repetition, reading, and writing abilities in different combinations. When aphasia is severe, there is usually some impairment of nonlanguage cognitive functions; when aphasia is global, dementia is obvious. With Broca or global aphasia, hemiparesis is usually severe. When aphasia is the result of a restricted posterior lesion, hemiparesis is mild. Aphasia in left-handed patients, regardless of the hemisphere involved, tends to be milder and resolves more rapidly than in right-handed patients with left hemisphere injury.

Left hemisphere convexity lesions, especially parietal, may cause bilateral ideomotor apraxia, in which the patient cannot perform learned motor acts on command but can describe the act and perform it when the setting is altered (e.g., after the examiner has given the patient an object the use of which the patient could not imitate). Buccolingual apraxia often accompanies Broca aphasia. Ideational apraxia (loss of understanding of the purpose of actions and difficulty manipulating objects) follows bilateral hemisphere damage and associated dementia. Infarction of the angular or supramarginal gyri of the dominant hemisphere can cause Gerstmann syndrome (i.e., agraphia, acalculia, left-right confusion, and finger agnosia).

Right hemisphere convexity infarction, especially parietal, causes disturbances of spatial perception; the patient has difficulty copying simple pictures or diagrams (constructional apraxia or apractognosia), interpreting maps, maintaining physical orientation (topographagnosia), or putting on clothing (dressing apraxia). Difficulty recognizing faces (prosopagnosia) is attributed to bilateral temporooccipital lesions. Hemineglect, a tendency to ignore the contralateral half of one's body or of external space, follows damage to the parietal lobe (or, rarely, the diencephalon), right more often than left. Patients may not recognize the hemiplegia (anosognosia), their arm (asomatognosia), or any external object to the left of their own midline. These phenomena can occur without visual field defects in patients who are otherwise mentally intact. Patients with right hemisphere convexity damage may have difficulty expressing or recognizing nonpropositional aspects of speech ("pragmatics"), such as emotional tone, sarcasm, or jokes. Right hemisphere lesions may also produce an acute confusional state.

Anterior Cerebral Artery

Infarction in the area of the anterior cerebral artery causes weakness, clumsiness, and sensory loss affecting mainly the distal contralateral leg. There may be urinary incontinence. Damage to the "supplementary motor area" may cause a speech disturbance that is considered aphasic by some physicians and a kind of motor inertia by others. There may be motor neglect, an apparent disinclination to use the contralateral limbs despite little or no weakness. Involvement of the anterior corpus callosum may cause tactile anomia or ideomotor apraxia of the left limbs, which is attributed to the disconnection of the left language-dominant hemisphere from the right motor or sensory cortex. If the damage includes the territory supplied by the major diencephalic branch (recurrent artery of Heubner), the anterior limb of the internal capsule is affected and the face or even the arm is also weak. Infarction restricted to structures supplied by the artery of Heubner (caudate nucleus and, variably, head of putamen and anterior limb of internal capsule) causes unpredictable combinations of dysarthria, abulia, agitation, contralateral neglect, and

language disturbance.

Bilateral infarction in the anterior cerebral artery region can cause a severe behavior disturbance, with apathy (abulia), motor inertia, muteness, incontinence, suck and grasp reflexes, and diffuse rigidity (gegenhalten) or total unresponsiveness with open eyes (akinetic mutism). Symptoms and signs are attributed to destruction of the orbitofrontal cortex, deep limbic structures, supplementary motor area, or cingulate gyri.

Posterior Cerebral Artery

Occlusion of the posterior cerebral artery most often causes contralateral homonymous hemianopia by destroying the calcarine cortex. Macular (central) vision tends to be spared because the occipital pole receives a collateral blood supply from the middle cerebral artery. Unilateral lesions are sometimes associated with visual perseveration (palinopsia) or release hallucinations in the blind field.

If the lesion affects the dominant hemisphere and includes the posterior corpus callosum, there may be alexia (without aphasia or agraphia) attributed to disconnection of the right occipital cortex (vision) from the left hemisphere (language). Such patients often have anomia for colors.

When infarction is bilateral, there may be cortical blindness, and sometimes the patient does not recognize or admit the loss of vision (Anton syndrome). Macular sparing, on the other hand, may produce tunnel vision. Other unusual phenomena of bilateral occipital injury are simultanagnosia (inability to synthesize the parts of what is seen into a whole), poor eye–hand coordination, difficulty coordinating gaze, metamorphopsia (distortion of what is seen, associated especially with occipitotemporal lesions), and visual agnosia.

Bilateral (and rarely unilateral) infarction in the posterior cerebral artery's supply to the inferomedial temporal lobe or medial thalamus causes memory disturbance, sometimes so severe and lasting as to resemble Korsakoff syndrome. It is possible that some cases of transient global amnesia represent transient ischemic attacks of this region. Patients with bilateral lesions affecting both the occipital and temporal lobes may present with agitated delirium.

If posterior cerebral artery occlusion is proximal, the lesions may include the thalamus or midbrain, which are supplied by interpeduncular, paramedian, thalamoperforating, and thalamogeniculate branches. Infarction of the ventral posterior nucleus causes severe loss of all sensory modalities on the opposite side or sometimes dissociated sensory loss with relative preservation of touch, proprioception, and discriminative modalities or conversely of pain and temperature sensation. As sensation returns, there may be intractable persistent pain and hyperpathia on the affected side (“thalamic pain,” “analgesia dolorosa,” or Roussy-Dejerine syndrome). A lesion of the subthalamic nucleus causes contralateral hemiballism.

Several abnormal eye signs may be found when posterior cerebral artery disease affects the midbrain: bilateral (or, less often, unilateral) loss of vertical gaze, convergence spasm, retractatory nystagmus, lid retraction (Collier sign), oculomotor palsy, internuclear ophthalmoplegia, decreased pupillary reactivity, and corectopia (eccentrically positioned pupil). Lethargy or coma follows damage to the reticular activating system. Peduncular hallucinosis, often consisting of formed and vivid hallucinations, can occur with infarcts restricted to either the thalamus or the pars reticulata of the substantia nigra. Posterior cerebral artery occlusion can cause contralateral hemiparesis by damaging the midbrain peduncle; it also causes contralateral ataxia by affecting the superior cerebellar outflow above its decussation.

Anterior Choroidal Artery

Infarction in the area of the anterior choroidal artery produces inconsistent deficits, with varying combinations of contralateral hemiplegia, sensory loss, and homonymous hemianopia that sometimes spares a beaklike zone horizontally (upper and lower homonymous sectoranopia). Responsible structures include the midbrain peduncle or posterior limb of the internal capsule and the lateral geniculate body or early optic radiations. Symptoms are often incomplete and temporary.

Internal Carotid Artery

Internal carotid occlusion may be clinically silent or may cause massive cerebral infarction. Damage occurs most often in the territory of the middle cerebral artery or, depending on collateral circulation, of one of its branches, with syndromes of varying severity. When the anterior communicating artery is not present, infarction may include the territory of the anterior cerebral artery. Internal carotid artery occlusion (or abrupt hypotension in someone with tight stenosis) can also cause infarction in the border zones (“watersheds”) between the middle, anterior, and posterior cerebral arteries; syncope at onset, focal seizures, and transcortical aphasia (relatively preserved repetition) are often seen with such lesions. When the posterior cerebral artery arises directly from the internal carotid, there may be symptoms referable to the visual cortex, thalamus, inferior temporal lobe, or upper brainstem. Infrequently, carotid artery disease causes vertebrobasilar transient ischemic attacks.

Emboli dislodged from atherosclerotic plaques in the internal carotid artery reach the retina through the ophthalmic and central retinal arteries to cause partial or complete visual loss. Platelet-fibrin or cholesterol emboli can sometimes be seen ophthalmoscopically in retinal artery branches.

Bilateral border zone infarction after severe hypotension can cause cortical blindness (from parietooccipital damage at the common border zone between the three major arterial territories) or brachial palsy (from bilateral rolandic damage at the border zone of the anterior and middle cerebral arteries).

Vertebrobasilar Arteries

Several eponyms have been applied to brainstem syndromes, but except for the lateral medullary syndrome of Wallenberg, most original descriptions concerned patients with neoplasms. Brainstem infarction is more often the result of occlusion of the vertebral or basilar arteries than of their paramedian or lateral branches; classic medial or lateral brainstem syndromes are encountered less often than incomplete or mixed clinical pictures ([Table 38.1](#)). That an infarct involves posterior fossa structures is suggested by bilateral long tract (motor or sensory) signs; crossed (e.g., left face and right limb) motor or sensory signs; dissociated sensory loss on one half of the body, with pain and temperature sensation more involved than proprioception; cerebellar signs; stupor or coma; dysconjugate eye movements or nystagmus, including internuclear ophthalmoplegia; Horner syndrome; and involvement of cranial nerves not usually affected by single hemispheric infarcts (e.g., unilateral deafness or pharyngeal weakness). Brainstem infarction may cause only unilateral weakness indistinguishable from that seen with lacunes in the internal capsule.

SYNDROMES OF INFARCTION

Lateral Medullary Infarction

This infarction usually follows occlusion of the vertebral or, less often, the posterior inferior cerebellar artery ([Fig. 38.6](#)). Manifestations include vertigo, nausea, vomiting, and nystagmus (from involvement of the vestibular nuclei); gait and ipsilateral limb ataxia (cerebellum or inferior cerebellar peduncle); impaired pain and temperature sensation on the ipsilateral face (spinal tract and nucleus of the trigeminal nerve) and the contralateral body (spinothalamic tract); dysphagia, hoarseness, and ipsilateral weakness of the palate and vocal cords and decrease of the gag reflex (nucleus ambiguus, or ninth and tenth nerve outflow tracts); and ipsilateral Horner syndrome (descending sympathetic fibers). There may be hiccup and, if the nucleus or tractus solitarius is affected, ipsilateral loss of taste. Some patients have loss of pain and temperature sensation over the contralateral and ipsilateral face (from involvement of the crossed ascending ventral trigeminothalamic tract) and some develop chronic pain, similar to “thalamic pain,” in the ipsilateral face or contralateral limbs ([Table 38.2](#)).

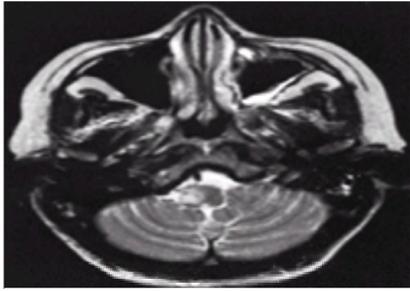

FIG. 38.6. T2-weighted axial magnetic resonance scan demonstrates a single focus of increased signal intensity within the posterior aspect of the right medulla, consistent with an early infarct. This infarct accounted for the patient's acute presentation with the lateral medullary syndrome of Wallenberg, secondary to occlusion of a branch of the right posterior inferior cerebellar artery. (Courtesy of Dr. S. Chan.)

Syndrome	Artery Affected	Structures Involved	Manifestations
Medial syndromes			
Medulla	Paramedian branches	Emerging fibers of 12th nerve	Ipsilateral hypoglossic of tongue
Inferior pons	Paramedian branches	Posterior gray column, near or in nucleus of 9th nerve	Paralysis of gaze to side of lesion
Superior pons	Paramedian branches	Emerging fibers of 5th nerve	Ipsilateral abduction paralysis
Medulla	Paramedian branches	Medial longitudinal fasciculus	Internuclear ophthalmoplegia
Lateral syndromes			
Medulla	Posterior inferior cerebellar	Emerging fibers of 9th and 10th nerves	Dysphagia, hoarseness, ipsilateral paralysis of larynx; ipsilateral loss of pharyngeal reflex
		Medullar nuclei	Vertigo, nystagmus
		Descending tract and nucleus of 11th nerve	Ipsilateral facial weakness
		Solitary nucleus and tract	Ipsilateral facial weakness
Inferior pons	Anterior inferior cerebellar	Emerging fibers of seventh nerve	Facial weakness
		Solitary nucleus and tract	Facial weakness
Medulla		Cochlear nuclei	Ipsilateral deafness
		Motor nucleus of 11th nerve	Ipsilateral facial weakness
		Emerging sensory fibers of 11th nerve	Ipsilateral facial numbness

TABLE 38.2. SIGNS THAT INDICATE THE LEVEL OF BRAINSTEM VASCULAR SYNDROMES

Infarction of Medial Medulla

An infarction of the medial medulla usually follows an occlusion of a vertebral artery or a branch of the lower basilar artery and involves the pyramidal tract, medial lemniscus, and hypoglossal nucleus or outflow tract. There is ipsilateral tongue weakness (with deviation toward the paretic side) and contralateral hemiparesis and impaired proprioception, but cutaneous sensation is spared.

Lateral Pontine Infarction

This may affect caudal structures when there is occlusion of the anterior inferior cerebellar artery or rostral structures after occlusion of the superior cerebellar artery. The caudal syndrome resembles that of lateral medullary infarction, with vertigo, nystagmus, ataxia, Horner syndrome, and crossed face-and-body pain and temperature loss. There is ipsilateral deafness and tinnitus (from involvement of the cochlear nuclei); if damage includes more medial structures, there is ipsilateral gaze paresis or facial weakness. Rostral lateral pontine infarction causes the same constellation of symptoms except that the seventh and eighth cranial nerves are spared and there is ipsilateral paresis of the jaw muscles.

Medial Pontine Infarction Syndromes

These syndromes occur after occlusion of paramedian branches of the basilar artery and depend on whether the lesion is caudal or rostral. A constant feature is contralateral hemiparesis. When the lesion includes the nucleus of the VIIth nerve, there is ipsilateral facial weakness; when damage is more rostral, facial paresis is contralateral. There also may be dysarthria (corticobulbar projections to the hypoglossal nucleus), ipsilateral gaze palsy (abducens nucleus or paramedian reticular formation), abducens palsy (VIIth nerve outflow tract), internuclear ophthalmoplegia (median longitudinal fasciculus), and limb or gait ataxia. Caudal lesions can cause contralateral loss of proprioception. Palatal myoclonus is attributed to involvement of the central tegmental tract and may be accompanied by rhythmic movements of the pharynx, larynx, face, eyes, or respiratory muscles.

Other Posterior Fossa Syndromes

A small infarct in the paramedian basis pontis affecting the pyramidal tract, nuclei of the basis pontis, and crossing pontocerebellar fibers can cause either ataxic hemiparesis, with contralateral weakness and cerebellar ataxia, or dysarthria clumsy-hand syndrome, with dysarthria and contralateral upper limb ataxia. Why the cerebellar signs should be entirely contralateral is unclear.

Symptoms resembling acute labyrinthitis, with vertigo, nausea, vomiting, and nystagmus, may accompany either infarction of the inferior cerebellum or occlusion of the internal auditory artery, which arises from the basilar or anterior inferior cerebellar arteries, with resulting infarction of the inner ear. Large cerebellar infarcts may mimic cerebellar hemorrhage, with headache, dizziness, ataxia, and, if there is brainstem compression, abducens or gaze palsy and progression to coma and death.

Drop attacks are caused by fleeting loss of strength or muscle tone without loss of consciousness; bilateral ischemia of the pontine or medullary pyramidal tract is the explanation in some cases. Infarction of the corticobulbar and corticospinal tracts in the basis pontis (sparing the tegmentum) causes the "locked-in syndrome," with paralysis of limbs and lower cranial nerves; communication by preserved eye movements reveals that consciousness is intact.

Midbrain Infarction

This follows occlusion of the posterior cerebral artery, but the classic mesencephalic syndromes (oculomotor palsy with contralateral hemiparesis, the Weber syndrome, or crossed hemiataxia and chorea, the Benedikt syndrome) are infrequently the result of stroke.

Bilateral Upper Brainstem Infarction

Infarction at this site causes coma by destroying the reticular activating system. When the level is pontine, signs mimic those caused by hemorrhage, with reactive miotic pupils and loss of eye movements. When damage is mesencephalic, ophthalmoplegia is accompanied by midposition unreactive pupils. Rostral midbrain lesions cause different kinds of supranuclear vertical gaze palsy—upward, downward, bilateral, or monocular. If there is only partial loss of consciousness, bilateral long tract motor and sensory signs or cerebellar ataxia may be detected.

Pseudobulbar Palsy

This is a syndrome that follows at least two major cerebral infarcts on different sides of the brain (which may occur at different times) or numerous lacunes on both sides. The bilateral hemisphere lesions cause bilateral corticospinal reflex signs (with or without major bilateral hemiparesis), supranuclear dysarthria and dysphagia (with impaired volitional movements but exaggerated reflex movement of the soft palate and pharynx), and emotional incontinence with exaggerated crying (or, less often, laughing) that is attributed to release of limbic functions. Other causes of pseudobulbar palsy are multiple sclerosis and amyotrophic lateral sclerosis.

Vascular Dementia

Cerebral infarction causes dementia by several mechanisms (Table 38.3). Dementia also can follow hemorrhagic stroke, and its frequent occurrence in patients with cerebral amyloid angiopathy suggests possible overlap between that condition and Alzheimer disease. Although some workers have proposed chronic potentially reversible cerebral hypoperfusion as a cause of dementia, most reject such a mechanism.

1. Critically located single infarcts.
a. Severe aphasia with additional cognitive impairment (middle cerebral artery).
b. Amnesia with bilateral inferomesial temporal or thalamic damage (posterior cerebral artery).
c. Abulia, memory impairment, or language disturbance with inferomedial frontal damage (anterior cerebral artery).
d. Acute confusion or psychosis with nonlanguage dominant parietal lobe damage (middle cerebral artery).
2. Multifocal dementia: Multiple large infarcts not necessarily in eloquent locations but usually destroying at least 100 mL of brain volume.
3. Small-vessel disease: Ranging from multiple small deep infarcts (lacunes) to more widespread patchy or diffuse ischemic lesions of the deep cerebral white matter. The latter condition, Binswanger disease, when severe produces abulia, abnormal behavior, pseudobulbar palsy, pyramidal signs, disturbed gait, and urinary incontinence. CT shows periventricular lucencies ("leuko-araiosis") and MRI reveals similarly located signal alterations. Such findings, however, are specific for neither cerebrovascular disease nor dementia.

CT; Computed tomography; MRI, Magnetic resonance imaging.

TABLE 38.3. PROPOSED MECHANISMS OF VASCULAR DEMENTIA

The diagnosis of vascular dementia is problematic, because the presence, revealed clinically or by imaging studies, of one or more strokes hardly proves causality, and coexisting Alzheimer disease can be excluded only pathologically.

CHAPTER 39. CEREBRAL AND CEREBELLAR HEMORRHAGE

J. P. MOHR AND CHRISTIAN STAPP

[Suggested Readings](#)

Most hemorrhages in the brain parenchyma arise in the region of the small arteries that serve the basal ganglia, thalamus, and brainstem and are caused by an arteriopathy of chronic hypertension. This disorder causes either occlusions with lacunar infarction or leakages that are brain hemorrhages. Other well-established risk factors include increasing age, cigarette smoking, alcohol consumption, and low serum cholesterol. Individuals of African, Hispanic, or Asian origin show a higher incidence of brain hemorrhage than do whites. A few hemorrhages arise from *congophilic amyloid angiopathy*, a degenerative disorder affecting the media of the smaller arteries, mainly of the cerebral gray matter in elderly individuals. Brain tumors, sympathomimetic drugs, coagulopathies, and small arteriovenous malformations also cause brain hemorrhages. Although treatment with anticoagulants or fibrinolytic agents encounter a higher risk of hemorrhage with increasing doses, the role of aspirin intake in this context is controversial.

Because most spontaneous hemorrhages arise from tiny vessels, the accumulation of a hematoma takes time and explains the smooth onset of the clinical syndrome over minutes or hours. The progressive course, frequent vomiting, and headache are major points that help to differentiate hemorrhage from infarction. Hemorrhage usually stops spontaneously by 30 minutes but in fatal cases continues until death is caused by brain compression or by disruption of vital structures. The *putamen* is the site most frequently affected. When the expanding hematoma involves the adjacent internal capsule, there is a contralateral hemiparesis, usually with hemianesthesia and hemianopia and, in large hematomas, aphasia or impaired awareness of the disorder. However, small self-limiting hematomas close to the capsular region may occasionally mimic lacunar syndromes featuring pure motor or sensory deficits. When the hemorrhage arises in the *thalamus*, hemianesthesia precedes the hemiparesis. Once contralateral motor, sensory, and visual field signs are established, the main points that distinguish the two sites are conjugate horizontal ocular deviation in putaminal hemorrhage and impaired upward gaze in thalamic hemorrhage.

Pontine hemorrhage usually plunges the patient into coma with quadriplegia and grossly disconjugate ocular motility disorders, although small hemorrhages may mimic syndromes of infarction. Primary spontaneous hemorrhages within the *mesencephalon* or the *medulla* remain objects of debate and are rare curiosities. When they occur, the anatomic involvement is usually secondary to hemorrhage originating in neighboring diencephalic, cerebellar, or pontine regions.

Among the *cerebral lobes*, there is a yet-unexplained predilection for hemorrhages to occur within the posterior two-thirds of the brain. When they affect one or more cerebral lobes, the syndrome is difficult to distinguish clinically from infarction because progressive evolution and vomiting are much less frequent; also, lobar white matter hematomas often result from arteriovenous malformations, amyloid angiopathy, tumors, or other causes that rarely affect the basal ganglia, thalamus, and pons.

Cerebellar hemorrhage warrants separate description because the mode of onset differs from that of cerebral hemorrhage and because it often necessitates surgical evacuation. The syndrome usually begins abruptly with vomiting and severe ataxia (which usually prevents standing and walking); it is occasionally accompanied by dysarthria, adjacent cranial nerve (mostly VIth and VIIth) affection, and paralysis of conjugate lateral gaze to one side, findings that may mislead clinicians into thinking the disease is primarily in the brainstem. However, a cerebellar origin is suggested by the lack of changes in the level of consciousness and lack of focal weakness or sensory loss. Enlargement of the mass does not change the clinical picture until there is enough brainstem compression to precipitate coma, at which point it is too late for surgical evacuation of the hemorrhage to reverse the disorder. This small margin of time between an alert state and an irreversible coma makes it imperative to consider the diagnosis in all patients with this clinical syndrome and a reason to have patients with vomiting of undetermined origin stand and walk when encountered in the emergency room. Computed tomography or magnetic resonance imaging should be carried out promptly, and surgery should be performed within hours on all the larger hemorrhages.

CHAPTER 40. GENETICS OF STROKE

ALEXANDER HALIM AND RALPH L. SACCO

[Cadasil](#)
[Intracerebral Hemorrhage](#)
[Subarachnoid Hemorrhage](#)
[Ischemic Strokes](#)
[Summary](#)
[Suggested Readings](#)

Numerous single-gene (Mendelian) disorders associated with ischemic or hemorrhagic stroke have been identified (e.g., sickle cell disease, Marfan syndrome, and Fabry disease). Many of these conditions are discussed elsewhere in this text. Although these disorders represent a direct genetic etiology of stroke, they are rare and do not account for a large proportion of stroke cases. Genetic factors may also indirectly influence vascular risk factors. Examples include genetic disorders associated with hypercoagulable states that increase the risk of venous thrombosis, metabolic disorders that lead to vasculopathy, and hereditary intracranial aneurysms that cause hemorrhagic stroke.

In 1993, a single gene was identified for the stroke syndrome, cerebral autosomal dominant inherited arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL). This may be the only stroke condition with a direct genetic etiology. Other types of epidemiologic studies suggest both genetic and environmental factors ([Table 40.1](#)).

Stroke Subtype	Chromosomal Map Location	Gene/Protein	OMIM
Ischemic stroke			
CADASIL	19p13.2-p13.1	Notch3 mutation	102918
Apolipoprotein C-III deficiency	19p13.2	apolipoprotein C-III mutation	227460
Hypofibrinolysis	21q22.3	plasminogen activator inhibitor-1	134630
Hypofibrinolysis	13q31.3	lysyl prolyl oxidase	228200
Marfan syndrome	15q21.1	FBN1	154900
Protein C deficiency	20p11.2	Protein C gene	176860
Protein S deficiency	3q27.3-q27.2	Protein S gene	176850
Stroke of unknown cause	Multiple	Stroke gene	Multiple
ICH			
Cerebral cavernous malformations	7q11.2-q21	Cerebral cavernous malformation 1	116668
Hemorrhagic stroke/hemorrhage with angiopathy			
Dutch type	21q21.3-q22.05	Amyloid precursor protein	104760
Icelandic type	20p13.2	Cystatin C	163050
SAH			
Marfan syndrome	15q21.1	FBN1	154900
Polycystic kidney disease	16p13.2-q13.12	PKD1	164700
	16p11.2-q11.2	PKD2	164710
	16p11.2	PKD3	613200

*Genes that have been identified for stroke are listed.
 OMIM: Online Mendelian Inheritance in Man; Notch3, cerebral autosomal dominant inherited arteriopathy with subcortical infarcts and leukoencephalopathy; ICH, intracerebral hemorrhage; SAH, subarachnoid hemorrhage.

TABLE 40.1. SOME GENETIC ETIOLOGIES OF STROKE

CADASIL

CADASIL is caused by a Notch3 mutation on chromosome 19. Most CADASIL pedigrees have come from western Europe; several pedigrees have been identified in the United States. Linkage to the D19S226 locus on chromosome 19 has been confirmed in over a dozen families, suggesting genetic homogeneity.

CADASIL is characterized by recurrent episodes of subcortical infarcts or transient ischemic attacks and a conspicuous absence of common stroke risk factors such as hypertension. Onset is between ages 30 and 50. The variable clinical manifestations include dementia, pseudobulbar palsy, and migraine. There is no specific treatment, and the mean survival is 20 years from onset.

In symptomatic patients magnetic resonance imaging (MRI) shows deep small infarcts in the subcortical white matter and basal ganglia. The leukoencephalopathy is extensive and can be patchy or diffuse. The U fibers are almost always spared. Skin biopsy can be diagnostic, showing granular, eosinophilic, electron-dense material in the media of the arterial wall. MRI is more sensitive than computed tomography, but the changes may be nonspecific. Skin biopsy is more specific than MRI but may not be more sensitive. Brain biopsy seems most sensitive and specific; granular, eosinophilic, electron-dense, nonamyloid material is found primarily in the walls of penetrating arteries in the white matter and leptomeningeal and basal ganglia arteries.

A phenotypic variant of CADASIL was identified by familial clustering of hemiplegic migraine and labeled CADASILM (“M” for migraine).

INTRACEREBRAL HEMORRHAGE

Intracerebral hemorrhages (ICH) may be caused by amyloid angiopathies. Dutch and Icelandic forms of hereditary cerebral amyloid angiopathy demonstrate the genetic influence in ICH. However, it is unclear how often ICH is hereditary or sporadic.

The Dutch form involves mutations in the amyloid precursor protein gene, and the Icelandic form is caused by a deletion mutation in the cystatin C gene on chromosome 20. Both are rare autosomal dominant diseases characterized by lobar hemorrhages and premature death in young adults without other cause of hemorrhage. The apolipoprotein E e2 and e4 alleles may be directly associated with cerebral amyloid angiopathy, and consequently with an increased risk for and earlier age at first hemorrhage.

Cerebral cavernous malformations often cause hemorrhages. A single abnormal gene causing cerebral cavernous malformation has been localized to chromosome 7q11.2-q21. However, it is difficult to discern whether an individual ICH results from familial or sporadic cavernous malformations.

SUBARACHNOID HEMORRHAGE

Familial aggregation of subarachnoid hemorrhages may be independent of hypertensive vascular disease, suggesting a strong genetic influence. Segregation analysis of intracranial aneurysms indicates the most likely pattern is either autosomal dominant with a rare susceptibility allele or autosomal recessive with a less rare susceptibility allele. The evidence for autosomal inheritance pattern is strong but of insufficient power to detect the true mode of inheritance. Genetic heterogeneity may be important. Cerebral aneurysms have been linked to type III collagen mutations and to several human leukocyte antigens.

ISCHEMIC STROKES

Twin studies suggest a possible genetic etiology of stroke; however, the role of genetics in ischemic strokes is unresolved. Variations in the incidence of ischemic stroke in racial groups support the notion of a genetic component. Alternatively, migration studies among Hawaiian residents of Japanese descent and other epidemiologic studies imply strong environmental risk factors. Relatives of people with ischemic stroke often share the same risk factors, making it difficult to separate genetic factors from shared environment.

Documented risk factors of ischemic stroke are under strong genetic influences. Hypertension, diabetes, heart disease, and obesity all have genetic influences that may or may not interact with environmental factors. Whether a predisposition to cigarette smoking is hereditary is controversial; observed clustering of smoking within families is often attributed to cultural rather than genetic causes. Several polymorphisms modify the effect of cigarette smoking on cancers, and some polymorphisms may influence stroke via an effect on atherogenesis. The observation of multiple cases of ischemic stroke within families could result from a high prevalence of any or all these risk factors in the population, or these may be a familial clustering of hereditary ischemic stroke that is specifically mediated through one or more of these

hereditary diseases.

Hypercoagulation states are risk factors for ischemic stroke and are under genetic control. Increased plasma fibrinogen levels, caused by a mutation of the beta-fibrinogen gene, are associated with increased risk of ischemic stroke. Hereditary hypercoagulopathies (protein C deficiency, protein S deficiency, antithrombin III deficiency, and activated protein C resistance due to the Leiden factor V mutation) can cause venous thrombosis, although the association with arterial thrombosis is uncertain.

Ischemic stroke and ischemic heart disease are associated with increased lipoprotein (a) levels that depend on the expression of the apolipoprotein A locus. The role of lipoprotein (a) on a population level and its relation to other stroke risk factors is uncertain.

Homocystinuria and hyperhomocysteinemia increase the risk of ischemic stroke. Both genetic and environmental conditions can cause these disorders. The most common form is homocystinuria, an autosomal recessive disorder caused by a deficiency of the cystathione-beta-synthetase enzyme that catalyzes the conversion of methionine to cysteine. The prevalence of homocystinuria is 1 per 200,000. Other genetic causes of elevated homocysteine levels include reduced plasma concentrations of methyl-tetrahydrofolate and methyl-cobalamin or decreased methylenetetrahydrofolate reductase activity.

SUMMARY

The determination of a genetic etiology for stroke would allow early identification of persons with increased risk of stroke through genetic screening. Except for using skin biopsy to detect CADASIL, genetic screening is not available for most stroke cases. In the case of CADASIL, the absence of effective treatment does not promote disease prevention despite the availability of genetic screening. Stroke prevention would therefore require the early intervention of stroke risk factors that have varying contributions of genetic and environmental influences. Genetic screening of Mendelian disorders may identify asymptomatic or undiagnosed risk factors and potentially prevent stroke.

LACUNAR STROKES

Occlusion of small penetrating arterioles (<500 μm diameter) usually follows sustained hypertension and leads to cystic cerebral degeneration or lacune formation. These small occlusions are frequently located in clinically silent areas, but well-defined lacunar syndromes have been described. These include pure motor hemiplegia, hemisensory stroke, sensorimotor pseudobulbar palsy, ipsilateral ataxia and hemiparesis, and dysarthria-clumsy hand syndrome. Fisher (1982) described over 20 discrete syndromes.

Pure motor hemiplegia usually involves the face, arm, or leg, or their combination, without sensory loss; the lacune disrupts the corticospinal tracts in the internal capsule or pons. As with other lacunar syndromes, diseases other than hypertension may cause identical symptoms; these include emboli and hemorrhage.

Pure hemisensory stroke without motor impairment is characterized clinically by numbness or paresthesias involving typically the face, arm, and leg. The impaired sensation can be explained by a lacune in the sensory nucleus of the thalamus. Pseudobulbar palsy results from multiple bilateral frontal lobe lacunes. Computed tomography may demonstrate lacunar hypodensities. When the lacunar syndrome can be explained adequately by hypertensive disease, no specific therapy other than hypertension control is indicated. The pathologic findings are of "lipohyalinosis," a degenerative process secondary to long-standing hypertension, although occasionally an atheromatous plaque of the feeding vessel can encroach onto the arteriole opening and cause ischemia.

HYPERTENSIVE ENCEPHALOPATHY

In 1928, Oppenheimer and Fishberg introduced the term *hypertensive encephalopathy* to describe encephalopathic symptoms (e.g., headaches, confusion, drowsiness, blurring of vision, occasional seizures, and infrequent focal signs) in association with an accelerated malignant phase of hypertension. The diastolic pressures are usually greater than 140 mm Hg and the fundi usually demonstrate grade IV changes with hemorrhages and disk edema. Children and pregnant or postpartum women show less elevated blood pressures to provoke hypertensive encephalopathy because their starting pressures are usually lower. Because this constellation of clinical findings may be found with strokes and systemic disorders (e.g., uremia and electrolyte imbalance), the diagnosis of hypertensive encephalopathy is frequently erroneous. The symptoms of hypertensive encephalopathy are reversed when blood pressure is reduced and renal function does not change. The syndrome is attributed to generalized arteriolar constriction with loss of cerebral autoregulation. Because the sustained hypertension may be life threatening, the therapeutic approach has been to treat these patients with hypotensive agents (e.g., sodium nitroprusside, labetalol) as demand therapy, unless stroke or some other conditions clearly explain the encephalopathic symptoms. If the symptoms do not improve, however, establishment of diagnosis is more difficult.

With hypotensive therapy, care must be taken not to reduce the blood pressure excessively because watershed infarcts are possible complications. A 15% to 20% reduction of mean arterial pressure but above the heightened lower end of autoregulation at approximately 125 mm Hg is initially desirable.

FIBROMUSCULAR HYPERPLASIA

Fibromuscular bands of unknown origin form segmental narrowing in large arteries and may cause ischemic symptoms of the brain, including transient ischemic attacks (TIAs) and infarcts, although they most frequently present as asymptomatic carotid bruits. Common involvement of the renal arteries leads to hypertension. Clinical diagnosis of fibromuscular hyperplasia is suggested by the combination of carotid and renal artery bruits in the presence of systemic hypertension. Women are usually affected in middle age. Diagnosis is rarely suspected before the lesions are demonstrated by angiography. Antiplatelet drugs, anticoagulation, and surgical dilatation have all been reported to reduce the frequency of TIAs.

MULTIINFARCT OR VASCULAR DEMENTIA

This syndrome is discussed elsewhere in the book.

CEREBRAL AMYLOID ANGIOPATHY

Cerebral amyloid angiopathy or "conophilic angiopathy" is uncommon; it presents clinically as intracerebral hemorrhages, usually after the fifth decade. Amyloid deposits are found in medium and small cortical and leptomeningeal arteries and are not associated with systemic amyloidosis. Intracerebral hemorrhage, particularly lobar in location, tends to recur within months or years, and multiple hemorrhages may occur simultaneously. Progressive dementia occurs in 30%, and features of Alzheimer disease are seen pathologically in 50%.

No therapy is known for the primary process; indications for hematoma evacuation are similar to those for other causes: location, mass effect, and declining sensorium. A familial Dutch form may be detected by the presence of gamma trace alkaline microprotein in serum.

ANTIPHOSPHOLIPID SYNDROME LUPUS ANTICOAGULANT AND ANTICARDIOLIPIN ANTIBODY SYNDROME

Lupus anticoagulants, a double misnomer because thrombosis (arterial and venous) occurs in conditions other than lupus, are immunoglobulins, usually IgG but occasionally IgM and IgA. *In vitro*, they inhibit coagulation by interfering with phospholipid-dependent coagulation tests without inhibiting *in vivo* activity of coagulation factors. Lupus anticoagulants were first described in patients with systemic lupus erythematosus and have been reported with drug-induced lupus, other autoimmune diseases, neoplasm, phenothiazines, and idiopathically. Antiphospholipid syndrome associated with thromboses are both arterial and venous. These conditions may be associated with a false-positive VDRL test and mild thrombocytopenia. When so-called lupus anticoagulants or anticardiolipin antibodies occur without associated diseases, the condition is referred to as "primary antiphospholipid syndrome." Treatment to prevent thrombosis should be directed to the primary underlying condition, but reported therapies to prevent thrombosis include corticosteroids, antiplatelet drugs, and anticoagulation. For anticoagulation, which is perhaps the best therapy, the international normalized ratio (INR) should be kept at at least 3.0 for optimum effects.

HYPERHOMOCYSTEINEMIA

Hyperhomocysteinemia, or the elevation of blood homocysteine, may result from several enzymatic defects either primarily or secondarily from the effects of a number of drugs. For example, impairment of the conversion of homocysteine to cystathionine by cystathionine- β -synthase, which requires vitamin B₆ (pyridoxine) is one example. Other pathways require folate or vitamin B₁₂. Hyperhomocysteinemia is associated with ischemic strokes and myocardial infarction. A prospective study to validate the beneficial effects of these vitamins in preventing strokes and myocardial infarction is in progress.

STROKE IN YOUNG ADULTS

Stroke in young adults is usually defined as those occurring before age 45. The incidence and causes differ from strokes occurring after age 65. Of all strokes,

approximately 25% occur before age 65. People younger than 45 account for about 20% of those under age 65, or 5% to 10% of all strokes.

Differential Diagnosis

Strokes in young adults include a wide variety of disorders that are less frequently seen in older adults. The diagnostic approach can be divided into the three major categories: vascular diseases, particularly those other than atherosclerosis related; cardioembolic causes; and blood-element abnormalities, which can be divided into those affecting erythrocytes, proteins, or platelets. Discussion of each disease causing strokes in young adults is beyond the scope of this chapter, but the more important entities are discussed ([Table 41.1](#) and [Table 41.2](#)).

TABLE 41.1. DIFFERENTIAL DIAGNOSIS OF STROKES IN YOUNG ADULTS

Cases	%

Embolism	20
Nonatherosclerotic arteriopathy	10
Coagulopathy/systemic	10
Peripartum	5
Uncertain causes (including oral contraceptives, migraine, and mitral valve prolapse)	35

Modified from Hart RG, Miller VT. *Stroke* 1983;14:110-114.

TABLE 41.2. CAUSES OF BRAIN INFARCTION IN YOUNG ADULTS IN THE LITERATURE

Vascular Diseases

Premature atherosclerosis, migraine, and dissection of the vessel wall are prominent disorders seen in young adults. Premature atherosclerosis is seen with diabetes mellitus or hypertension and other known risks for atherosclerosis, such as smoking and elevated serum lipids; these people show evidence of diffuse vascular disease and often have TIAs before the stroke. These attacks are treated just as they are in older subjects, including carotid endarterectomy for symptomatic carotid stenosis and antiatherogenic measures.

Migraine may cause strokes in young adults. Although most have had migraine headaches chronically, the headache may or may not coincide with the stroke. The most common strokelike symptoms associated with migraine or so-called complicated migraine are aphasia, hemiparesis, and vertebrobasilar insufficiency. The goal of the treatment is to prevent the attacks of vasospasm. A young woman who takes oral contraceptives, including low-dose estrogens, seems to be at increased risk for these attacks; if one occurs, oral contraceptive use should be discontinued.

In addition, arteritis and strokes resulting from drug abuse are distinctly more common in young adults. Usually, the arteritides involving cerebral vessels become symptomatic after systemic manifestations of the disease have been present as in polyarteritis nodosa, Sjgren disease, and lupus erythematosus. However, isolated angiitis of the central nervous system or spinal cord is unusual in displaying few peripheral symptoms, signs, or serologic evidence of immune complex disorders; even the cerebral angiogram may be normal. If a young adult experiences multifocal brain disease, with obtundation, severe headaches, and no discernible systemic cause, a brain and leptomeningeal biopsy may be needed to diagnose isolated angiitis of the central nervous system (see [Chapter 155](#)).

Drug abuse can lead to strokes from arteritis or occlusive disease. Cerebral hemorrhage can occur with use of amphetamines or cocaine, and intravenous drug use may lead to bacterial endocarditis with bacterial/fibrin emboli or mycotic aneurysms in the brain. For drug-related strokes, both clinical history and drug screening are critical in establishing a diagnosis.

Cardiogenic Emboli

Of the causes of embolic strokes of cardiac origin, mitral valve prolapse is perhaps the most common, except for arrhythmias, although increasing attention is paid to the patent foramen ovale as a cause of cryptogenic strokes. Mitral valve prolapse is found in 10% to 15% of the population and more frequently in women; it is detected by a midsystolic click on auscultation and more specifically by two-dimensional echocardiography. Transesophageal echocardiography may be needed to supplement the transthoracic study by visualizing the posterior mitral leaflets. Risks of embolization, congestive heart failure, and cardiac arrest are substantially increased in the presence of leaflet redundancy, without which mitral valve prolapse is relatively benign. When redundancy is detected, treatment includes efforts to minimize embolization with antiplatelet drugs or, on occasion, anticoagulation.

With patent foramen ovale, mechanical patency is present in about one-fourth of the population. The pathogenic abnormalities are larger patent foramen ovals with paradoxical emboli with right-to-left shunting of venous emboli. In practice, vigorously shaken saline is injected to observe for the appearance of echogenic bubbles (>25) in the left atrium. Transcranial Doppler studies may detect emboli in the common carotid or middle cerebral arteries. If reembolization occurs despite adequate anticoagulation, surgical closure of the patent foramen ovale may be necessary.

Blood Element Abnormalities

Each constituent of blood may be a source of strokes in young adults, as in other age groups, including the cellular and protein components. The cellular elements include erythrocytes; most notable disorders are sickle cell anemia and polycythemia vera. With the advent of both noninvasive testing of intracranial and extracranial vessels and magnetic resonance imaging, stroke syndromes in sickle cell anemia are found to be complicated by the hyperviscosity state that provokes premature atherosclerosis of larger arteries and causes watershed ischemia and infarcts. Efforts to minimize stroke complications with transfusions and hydroxyurea to increase synthesis of fetal hemoglobin may be helpful.

Abnormalities of protein elements may give rise to stroke syndromes by influencing coagulation or viscosity of platelet aggregation. The role of antiphospholipid antibodies in causing strokes in young adults is reviewed above. As seen in [Table 41.1](#), multiple coagulation defects are associated with ischemic strokes and cortical vein thrombosis, but the most common is resistance to protein C activation. Its primary treatment to avert thrombosis is anticoagulation to keep the INR between 2.0 and 3.0.

CHAPTER 42. DIFFERENTIAL DIAGNOSIS OF STROKE

MITCHELL S.V. ELKIND AND J.P. MOHR

[Suggested Readings](#)

The potential for thrombolytic therapy for acute ischemic stroke has made the prompt distinction of cerebral infarction from hemorrhage and other causes of sudden neurologic deficit an important practical matter. Because treatment must be initiated within 3 hours of onset of symptoms, the differential diagnosis must be considered and an accurate diagnosis made very rapidly. Libman et al. (1995) studied 411 patients who received an emergency room diagnosis of stroke. Of those, 81% received a final diagnosis of stroke and a full 19% were determined to have one of several stroke “mimics.” These most commonly included seizures, systemic infection, brain tumor, and toxic-metabolic encephalopathy. Less frequent sources of misdiagnosis were positional vertigo, cardiac events, syncope, trauma, subdural hematoma, herpes simplex virus encephalitis, transient global amnesia, dementia, demyelinating disease, C-spine fracture, myasthenia gravis, parkinsonism, hypertensive encephalopathy, and conversion disorder. In multivariate analysis, factors that predicted a “true stroke” were the presence of angina and absence of loss of consciousness.

Within the category of cerebral infarction, a diagnosis of *cerebral embolism* is suggested by a sudden onset and a syndrome of circumscribed focal deficit attributable to cerebral surface infarction, such as in pure aphasia or pure hemianopia. The more complex the neurologic syndrome, the larger the arterial territory involved, the more proximal in the arterial tree that the occlusion occurs, and the more the diagnosis of *thrombosis* must be considered. A diagnosis of embolism is important because the risk of recurrence is high. The source of the embolus may be found in acute or chronic endocarditis, atrial fibrillation, recent myocardial infarction, or patent foramen ovale. The brain is the first site of symptoms in most cases of systemic embolism; clinically recognized embolization at other anatomic sites is rare. When the source of embolization is not obvious on hospital admission, useful procedures include routine blood cultures, electrocardiogram monitoring, and echocardiography. The size of the embolic material sufficient to cause a focal stroke is often too small to allow its exact source to be detected and all too often eludes all efforts at diagnosis. The cause of the embolus cannot be determined in a third or more of cases despite full use of laboratory investigations. Angiography within 24 hours of stroke usually demonstrates a pattern of arterial occlusion that is typical of embolus and permits diagnosis, but angiography is infrequently used. Brain imaging [computed tomography (CT) or magnetic resonance imaging (MRI)] allows the diagnosis of a focal infarction and allows inference of the size of the occluded artery. Modern CT and MRI appear positive for infarction within 24 hours if the artery occluded supplies a brain region sufficiently large to cause a deficit that persists for several days.

A diagnosis of thrombosis is considered first when the stroke has been preceded by transient ischemic attacks (TIAs). When the syndrome is of sudden onset, thrombus is clinically inseparable from embolus. No specific clinical syndrome separates the two mechanisms of infarction.

Hemorrhage has a characteristically smooth onset that is a helpful historical point in differential diagnosis. When the syndrome develops to an advanced stage within minutes or is halted at an early stage with only minor signs, the smooth evolution may not be apparent, and the clinical picture may then be inseparable from that of infarction. The hyperdense signal of blood on CT can immediately separate the clinically inobvious hemorrhage from infarct and should be used whenever treatment with anticoagulants is planned. Exceptional cases have been reported in which the typical hyperdensity characteristic of intracerebral hemorrhage was absent because of severe anemia, but this is unlikely to cause problems clinically. There are no reliable CT findings to distinguish hemorrhagic infarction and frank hematoma. The greater sensitivity to blood signal of MRI enables it to show a higher frequency of hemorrhagic infarction than is seen with CT.

The suddenness of onset and the focal signs give these syndromes the popular term “stroke” and distinguish cerebrovascular disease from other neurologic disorders. Hypertension, cardiac disease, arteriosclerosis, or other evidence of vascular disease are commonly present in cerebrovascular disease as well, unlike in other neurologic causes of focal deficit.

The distinction between TIA and completed stroke has been rendered less important since the advent of MR imaging has allowed detection of small fixed lesions that previously would have been missed. The traditional definition of TIA as a focal deficit lasting up to 24 hours greatly exaggerates the length of time needed for infarction to appear. Recent evidence suggests that 50% of patients with transient deficits lasting less than 24 hours will have evidence of ischemia on diffusion-weighted MR imaging and that 50% of those with diffusion-weighted abnormalities will have evidence of fixed infarction on subsequent T2-weighted images. In the acute state, considerations of differential diagnosis apply equally to TIA and stroke.

Sudden onset also characterizes trauma, epilepsy, and migraine. External signs usually indicate trauma, but when absent, diagnosis depends on a history that is not always easily obtained. It is important to remember that signs of external trauma need not be present for acceleration-deceleration forces to cause focal traumatic injury. The most frequent sites of brain contusions are the frontal and temporal poles, but these lesions neither produce an easily recognized clinical picture nor one often encountered in cases of stroke; however, epidural and subdural hematomas occur in a setting of trauma and may mimic a stroke. Although the trauma itself is sudden, the accumulation of the hematoma takes time: minutes or hours for epidural hemorrhage and as long as weeks for subdural hemorrhages.

Epidural hemorrhage is arterial in origin and usually produces a blood mass large enough to displace the brain and cause coma within hours after the injury. Apart from slower evolution, the clinical picture is otherwise similar to that of putaminal hemorrhage. Radiographs of the skull may reveal a fracture line that passes through the groove of the middle meningeal artery, which is usually a laceration. CT is the most helpful radiologic test; it demonstrates the position of the hematoma in all cases and gives the diagnosis even in comatose patients, when the fine points of clinical examination cannot be used. Surgical evacuation of the hematoma is usually appropriate even in cases with severe deficits because the brain dysfunction is due primarily to compression and the syndrome may be reversible when pressure from the hematoma has been relieved.

Subdural hematoma is typically venous in origin. The bleeding may be recurrent. The precipitating trauma may have been trivial or forgotten, and the blood may have been present long enough (over a week) to become isodense (radiographically inapparent) on CT or MRI. Fluctuating and false localizing signs are frequent. Further, a clot may be found on both sides. These common features often make subdural hematoma difficult to diagnose. Lumbar puncture shows a range of findings from normal to the extremes of xanthochromic cerebrospinal fluid (CSF) under high pressure with increased protein content. MRI has displaced angiography as the best means for showing the displacement of brain away from the skull.

As a sign of acute stroke, *seizures* are rare except in cases of lobar hemorrhage. The immediate postictal deficit mimics that caused by major stroke. Only the obtundation and amnesic state help suggest prior seizure. In a small percentage of cases, seizures develop months or years after a large infarct or hemorrhage. In these, the postictal state often represents a relapse of the original stroke syndrome, which usually resolves toward the chronic preictal state after a few days. Without a proper history, it may be nearly impossible to rule out new stroke. Rarely, seizures occurring in a patient with a prior stroke appear to have caused a long-lasting or permanent worsening or intensification of the prior deficit, without evidence of recurrent infarction. The mechanism by which this unusual event occurs is unknown.

Migraine is increasingly appreciated as a major source of difficulty in the diagnosis of TIA. Migraine may begin in middle age; the aura alone, without headache, is commonly experienced by those who suffer chronic migraine. When symptoms are visual and a diagnosis of transient monocular blindness is considered, the differential diagnosis from migraine is the easiest: Migraine typically produces a visual disorder that marches across the vision of both eyes as an advancing thin scintillating line that takes 5 to 15 minutes to pass out of vision. Subsequent unilateral pounding headache need not occur but makes the diagnosis certain. It is difficult to diagnose migraine as a cause of symptoms of hemisphere dysfunction because the auras of classic migraine only rarely include motor, sensory, language, or behavioral elements. TIA rarely goes from one limb to another like the visual disorder of migraine. A diagnosis of migraine probably should not be seriously considered as an explanation for transient hemisphere attacks unless the patient is young, has repeated attacks, experiences classic visual migraine auras at other times, and has a pounding headache contralateral to the sensory or motor symptoms in the hours after the attack. Recent studies of conditions long-recognized clinically, such as familial hemiplegic migraine and the familial periodic ataxias, have demonstrated mutations in ion channel genes as the cause of some cases of transient stroke-like deficits. Familial hemiplegic migraine, for example, is caused by a mutation in a calcium channel gene on chromosome 19. These syndromes are generally recognized by the recurrence of stereotypic episodes throughout life in patients with an appropriate family history. Occasionally, sporadic cases may be seen in which the diagnosis of TIA has been entertained for years.

As indicated above, brain tumor and abscess may mimic TIA or stroke. Both usually evolve in days or weeks, which is longer than stroke, but may present with acute transient symptoms. It is commonly thought but rarely proven that intratumoral hemorrhage or focal seizure is responsible for many of these cases. One helpful

historical point is that seizures often occur before focal signs are evident, a sequence that is rare in stroke. CT in tumor or abscess usually demonstrates an enhancing mass even when symptoms are mild. In contrast, CT in ischemic stroke is often negative in the first few days, contrast enhancement may not occur, and there are signs of a mass only when the syndrome is severe. In parenchymatous hemorrhage, the areas around the hematoma do not usually enhance with contrast material, but contrast enhancement is common when hemorrhage has occurred into a tumor. If the CSF is examined, increased pressure and clear or slightly cloudy fluid are encountered equally in tumors, early abscesses, and large infarcts. The CSF usually shows mild or moderate pleocytosis in abscess, but the same findings may be present in large infarcts.

When coma is present, other diagnoses that must be considered include metabolic disturbances of glucose, renal function, electrolytes, alcohol, and drugs. The odor of acetone on the breath and the presence of sugar in the urine favor a diagnosis of diabetes mellitus. Transient mild glycosuria and hyperglycemia often follow cerebral hemorrhage or infarction but do not approach the elevations seen in diabetic coma. In renal failure, high levels of blood urea nitrogen and creatinine often cause coma. Focal signs occasionally occur and then remit when the cause is reversed, often accompanying unrecognized infection or severe disturbances in electrolyte balance. Not uncommonly, however, focal deficits do not reverse themselves immediately, particularly when the metabolic derangement, such as hypoglycemia, has been profound. An alcoholic odor to the breath, normal blood pressure, no evidence of hemiplegia, and a normal CSF are characteristic findings in cases of coma due to acute alcoholism. In barbiturate intoxication, the coma may feature total paralysis of ocular motility and flaccid paralysis of the limbs with preserved pupillary reactions, which is a rare combination in stroke. The CSF pressure may be slightly elevated (200 to 300 mm H₂O) in any form of coma due to hypoventilation and CO₂ retention. Because alcoholics and drug abusers are prone to head injuries, the diagnosis of subdural hematoma should always be considered and excluded with appropriate imaging tests.

CHAPTER 43. STROKE IN CHILDREN

ARNOLD P. GOLD AND ABBA L. CARGAN

[Incidence](#)
[Clinical Evaluation](#)
[Clinical Evaluation](#)
[Etiology](#)
[Arterial Thrombosis](#)
[Cerebral Embolism](#)
[Intracranial Hemorrhage](#)
[Metabolic Disorders](#)
[Suggested Readings](#)

Children are not small adults when it comes to the diagnosis of stroke. In contrast to adults, the brain of the fetus or child is rapidly changing in organization and chemical composition. Neurologic functions change with neurologic maturation. The nervous system of a nonverbal relatively spastic newborn is different from that of a school-aged child who has mastered language skills and has purposeful locomotion and prehension.

Strokes in children differ from those in adults in three important ways: predisposing factors, clinical evolution, and anatomic site of pathology.

Cyanotic heart disease is one of the most common childhood conditions that predisposes to cerebral arterial or venous thrombosis. Leukemia commonly leads to cerebral hemorrhage. In contrast, atherosclerosis and hypertension predispose to stroke in adults.

Most stroke-prone children do not die as a direct result of stroke; they often improve much more than an adult with a comparable lesion because of the abundant collateral circulation or because of the differences in response of the immature brain to the lesion. The infant or young child with a new hemiplegia usually recovers to the point of being able to walk. If a child younger than age 4 years has a stroke, speech is invariably recovered and permanent aphasia does not occur. Children, especially before age 2 years, are more prone to behavioral changes, intellectual impairment, and epilepsy.

The anatomic site of the stroke lesion also differs in children. For example, affected children commonly show occlusion of the intracranial portion of the internal carotid artery and its branches, whereas adults more frequently show extracranial occlusions of the internal carotid. Cerebral aneurysms in children usually occur at the peripheral bifurcations of cerebral arteries; in adults, cerebral aneurysms usually occur near the circle of Willis.

INCIDENCE

In a well-defined pediatric population in Rochester, Minnesota, the annual incidence of cerebrovascular disease was 2.52 cases per 100,000 children or about 50% the incidence of primary intracranial neoplasm. This figure did not include conditions associated with birth, infection, or trauma, and there were few African-American children in the study. Cerebrovascular complications occur in 6% to 25% of patients with sickle cell disease; an untreated child with sickle cell disease has a 67% risk of a second stroke. Premature infants weighing less than 1500 g who require intensive care for more than 24 hours have a 50% incidence of complicating subependymal hemorrhage or intraventricular hemorrhage. Intracranial infections, viral or bacterial, may also precipitate vascular complications. Craniocerebral trauma occurs in 3% of children during the first 7 years of life and cerebrovascular complications are common. Sonography, magnetic resonance imaging (MRI), and computed tomography (CT) ([Fig. 43.1](#), [Fig. 43.2](#), [Fig. 43.3](#) and [Fig. 43.4](#)) are changing our concepts of the incidence of these disorders in children.

FIG. 43.1. Coronal cranial sonogram of newborn demonstrates aneurysmal dilatation of vein of Galen due to deep midline vascular malformation.

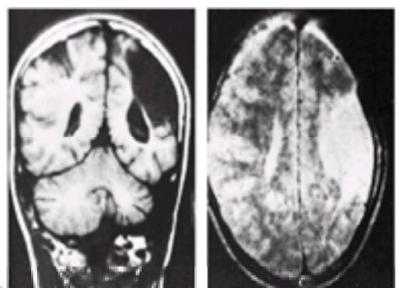

FIG. 43.2. Magnetic resonance images of a child with middle cerebral artery thrombosis and resultant hemiplegia with ischemic infarct. **A:** T1-weighted coronal image. **B:** Axial T2-weighted image of left middle cerebral artery ischemic infarct.

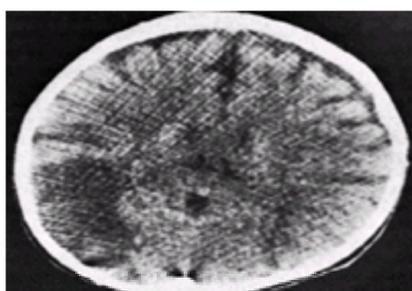

FIG. 43.3. Middle cerebral artery thrombosis of 24-hour duration. Computed tomography reveals inhomogeneous hypodensity with hazy margins in the parietooccipital region (early scanner, right and left reversed).

Mitochondrial myopathy, encephalopathy, lactic acidosis, and strokelike episodes (MELAS)
Migraine

ARTERIAL THROMBOSIS

Cerebral arterial thrombosis in children usually involves the intracranial area of the internal carotid artery, although the cervical portion of the internal carotid artery or a spinal artery may be occluded. Neurologic manifestations vary according to the area involved.

As in adults, systemic diseases, including collagen-vascular diseases and arteritis, may cause cerebral thrombosis in children. Cerebral arteritis usually results from bacterial infections, but other infections may also involve cerebral arteries. Herpes zoster ophthalmica and rarely chickenpox may have complicating vasculitis that causes delayed-onset hemiparesis. Bacterial pharyngitis, cervical adenitis, sinusitis, or pneumonitis may lead to cerebral arteritides. Mucormycosis infection associated with uncontrolled diabetes may extend from the paranasal sinuses to the arteries in the frontal lobe. Both syphilis and tuberculosis may result in cerebral thrombosis in children and adults.

Extrinsic conditions may traumatize or compress the cerebral arteries. Most of these occlusions in children affect the anterior circulation. Vertebrobasilar occlusion may follow cervical dislocations and occlusion of the vertebral artery at the C2 level. Tumors of the base of the skull, craniometaphyseal dysplasia, and retropharyngeal abscesses may compress cerebral arteries.

Sickle cell disease commonly causes thrombosis of large or small arteries; less commonly, it results in dural sinus thrombosis. Approximately 7% to 11% of patients with sickle cell disease have stroke before the age of 20 years. Large cerebral artery thrombosis with telangiectasia (moyamoya) results in acute hemiplegia or alternating hemiplegia ([Fig. 43.5](#)). Small arterial thrombosis can produce an altered state of consciousness, convulsions, or visual disturbances. About 65% of untreated children have repeated thromboses with additional impairment of motor and intellectual functions. Radiographic progression in the absence of clinically overt deficits suggests increase in the stroke risk with time and underscores the importance of treatment. Cerebrovascular complications are less common in children with sickle hemoglobin C disease and rarely occur in sickle cell trait. MRI, magnetic resonance angiography, and diffusion-weighted imaging have become invaluable tools in defining stroke events in children, and transcranial Doppler is a useful adjunct for follow-up and screening.

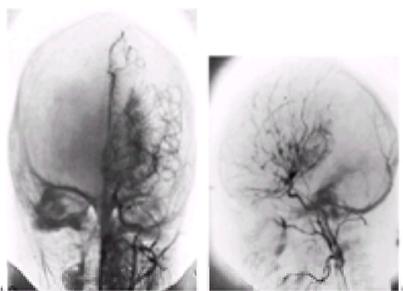

FIG. 43.5. Moyamoya syndrome. Anteroposterior (A) and lateral (B) views from arterial phase of left common carotid arteriogram demonstrate multiple enlarged and serpentine lenticulostriate arteries, which have a “puff of smoke” appearance. Note occlusions of the proximal segments of the anterior and middle cerebral arteries.

Migraine may be manifested by hemiplegia or visual field defects. MRI changes are nonspecific, but punctate periventricular white matter changes are often attributed to migraine. MELAS should be considered when stroke accompanies migraine in a child.

Inflammatory bowel disease may lead to a hypercoagulable state with or without thrombocytosis. Delayed radiation vasculopathy, juvenile diabetes mellitus, homocystinuria, hyperlipidemias, drug abuse, and oral contraceptives result in acute hemiplegia.

Malignancies, most commonly lymphoreticular tumors, may be complicated by a cerebral infarct. Most often this is a complication of disseminated vascular occlusion or chemotherapy. Stroke may also result from direct metastatic spread or a complicating thrombocytopenia or fungal infection.

Coagulopathies may become evident with a thrombotic event. Protein C and protein S deficiencies increase the risk of stroke in childhood. Factor V Leiden deficiency also predisposes to cerebral vessel thrombosis.

Many children with cerebral arterial thrombosis are healthy before the vascular occlusion occurs and there is no apparent predisposing factor. A dissecting aneurysm due to a congenital defect of the arterial wall has been implicated in some of these idiopathic cases.

Signs and Symptoms

Depending on the predisposing factor, the child with arterial thrombosis has specific clinical signs of the underlying disorder plus neurologic signs of the occluded cerebral artery that are usually found in the anterior circulation. A previously healthy child usually has an acute hemiplegia that is preceded by focal or generalized convulsions, fever, and altered consciousness; less commonly, a series of transient ischemic attacks eventually results in a completed stroke. Acute hemiplegia is the typical neurologic finding, but hemisensory loss, visual field defects, and aphasia may be seen. The disorder maximally involves the hand; if it persists, the involved limbs are spastic, short, and atrophic. Seizures, focal or generalized, are often refractory to anticonvulsants.

The hemiplegia is usually an isolated episode. Bilateral carotid artery thrombosis with telangiectasia typically presents with headaches before the hemiplegia, and recurrences or alternating hemiplegia is characteristic.

Laboratory Data

Blood count, erythrocyte sedimentation rate (ESR), and urinalysis are normal at the time of thrombosis. The cerebrospinal fluid (CSF) is normal at first, and a mild leukocyte pleocytosis may occur a few weeks later. The electroencephalogram often reveals a slow-wave focus over the involved area. Although skull radiographs are normal when thrombosis occurs, after several years they may show signs of cerebral atrophy with thickening of calvarium, enlargement of the frontal and ethmoid sinuses, and elevation of the petrous pyramid of the temporal bone on the involved side.

CT supplies information about the site and age of the infarct. Within 24 hours there is a nonhomogeneous decreased-density lesion secondary to edema ([Fig. 43.3](#)). By the end of the first week, liquefaction necrosis develops, and the infarct becomes homogeneous with defined margins ([Fig. 43.4](#)). At 3 months, the necrotic infarct is replaced by a cystic fluid-containing cavity, and the lesion with sharp margins has the homogeneous density of CSF.

Sonography is invaluable in defining cerebral anatomy and hemorrhagic complications in the infant, especially the premature infant ([Fig. 43.1](#)). MRI has become an important diagnostic tool in the early diagnosis of ischemic lesions ([Fig. 43.2](#)). Magnetic resonance angiography is useful in defining the major portions of large- and medium-size vessels of the intracranial circulation. magnetic resonance venography is helpful in the diagnosis of venous sinus thrombosis if there are changes in vascular outflow. Diffusion-weighted MR imaging is gaining prominence in diagnostic evaluation. Echo-planar diffusion-weighted MR imaging reveals acute and hyperacute ischemia not seen on conventional spin-echo imaging.

Arteriography, when performed early, may demonstrate the thrombosed cerebral artery; later there may be a recanalized vessel or evidence of collateral circulation. Cerebral angiography can usually be performed safely in children of all ages. The patency of other cerebral arteries and the ample collateral circulation in children contrast with the status of the cerebral arteries and collateral circulation in adult stroke patients. Children with sickle cell disease are at greater risk if the level of

hemoglobin S is not maintained at a level below 20% by exchange transfusion.

The following practical angiographic classification was formulated by Hilal et al. (1971) to supply diagnostic and prognostic information for the following patterns.

Extracranial Occlusion

Trauma is the most common cause of thrombosis of the cervical portion of the internal carotid artery. Blunt trauma in the paratonsillar area of the oropharynx or direct impact of the carotid artery against the transverse process of the second cervical segment can cause occlusion. Characteristically, about 24 hours lapse between the traumatic incident and clinical manifestations. Nontraumatic conditions are usually infectious in origin.

Basal Occlusion Disease Without Telangiectasia

The thrombotic lesion involves the arteries of the base of the brain: supraclinoid area of the internal carotid artery, proximal segments of anterior or middle cerebral artery, or basilar artery. The condition is unilateral and does not recur.

Basal Occlusive Disease with Telangiectasia (Moyamoya)

This condition involves the arteries at the base of the brain, is often bilateral, and is associated with prominent telangiectasia, especially in the region of the basal ganglia (Fig. 43.5). Of varied etiology, it may complicate sickle cell disease, bacterial or tuberculous meningitis, or neurofibromatosis; it may also complicate the treatment plans of radiotherapy. Recurrent episodes of thrombosis are common and may result in alternating hemiplegia, epilepsy, and learning disabilities. Neuropsychological testing has demonstrated the benefit of surgical intervention in preventing further deterioration of function.

Peripheral Leptomeningeal Artery Occlusions

Branch occlusions of the distal leptomeningeal arteries may occur with diabetes mellitus, sickle cell disease, trauma, infection, tumor encasement, or neurocutaneous syndromes. The excellent collateral circulation usually results in rapid recovery from the acute hemiplegia.

Perforating Artery Occlusion

Involvement of the small perforating arteries, most commonly the striate arteries, is seen in children with homocystinuria or periarthritis nodosa. Episodes recur, causing a progressive neurologic deficit with alternating hemiparesis or quadriplegia, subarachnoid hemorrhage, or death.

Treatment

Therapeutic measures may include parenteral fluids, antibiotics when indicated, anticonvulsants, anticoagulants to prevent extension of the thrombus, and variations of the agents to control increased intracranial pressure. Variations of the syngiosis procedure are used to enhance circulation to ischemic areas of the brain in moyamoya. Anastomoses of external carotid to internal carotid arteries are not feasible because the arteries of the child's brain are too small in diameter. Instead, the superficial temporal artery is attached to the surface of the brain, allowing the formation of a rich collateral network, which supplies parts of the brain that would otherwise be ischemic.

Anticoagulants are rarely indicated except when a stroke is in progress. Rarely does arterial thrombosis result in sufficient increased pressure to require intracranial pressure monitoring or measures to reduce intracranial pressure. Bilateral cervical sympathectomies to increase regional blood flow and anastomosis of the external and internal carotid arteries have been of dubious value.

Sickle cell disease is treated by repeated blood transfusions. The risk of future strokes is reduced by a long-term transfusion program to maintain hemoglobin S at a level below 20%. This has been demonstrated in clinical trials that have looked at accumulation of neurologic deficits and radiographic evidence of ischemic events.

CEREBRAL EMBOLISM

In cerebral embolism, an artery can be occluded by air, fat, tumor, bacteria, parasites, foreign body, or a fragment from an organized thrombus. The middle cerebral artery or its branches are most commonly involved.

Cerebral embolism in childhood is usually cardiogenic, especially after cardiac catheterization or open heart surgery but is also seen with cardiac arrhythmias due to cyanotic congenital heart disease or rheumatic valvular disease, bacterial endocarditis, or atrial myxoma. Septic embolism from pulmonary inflammatory disease or bacterial endocarditis may result in brain abscesses or mycotic aneurysms. Fat embolism is an unusual complication of long-bone fractures.

Signs and Symptoms

The focal neurologic signs vary according to the artery occluded; manifestations are complete within seconds or minutes. There are also signs and symptoms of the causal disorder: transient blindness with air embolism; petechiae and hematuria with septic emboli; cutaneous petechiae, urinary free fat, and fat in the retinal vessels with fat emboli due to long-bone fracture or intravenous fat infusions.

Fat embolism has a characteristic clinical picture. A lucid interval of 12 to 48 hours occurs after a long-bone fracture. The child then becomes febrile with pulmonary symptoms that include dyspnea, cyanosis, and blood-tinged sputum. Within a few hours, there is an acute encephalopathy that may include focal neurologic signs, diabetes insipidus, seizures, delirium, stupor, or coma.

Laboratory Data

Routine laboratory studies after cerebral embolism are often normal, but a moderate polymorphonuclear leukocytosis may be present. The CSF is usually normal, but there may be a mild elevation of the protein content. Septic embolism in bacterial endocarditis may cause an elevated CSF protein content and pleocytosis. Atrial myxomas commonly show peripheral blood leukocytosis, anemia, and an elevated ESR. The electroencephalogram characteristically shows a slow-wave abnormality in the areas supplied by the occluded vessel.

MRI is often characteristic in showing multiple infarcts, some of which are hemorrhagic (Fig. 43.6). The lesions become lucent with sharp margins 2 to 3 months later. Diffusion-weighted imaging and fluid attenuated inversion recovery FLAIR MRI studies assist the rapid detection of stroke events. Lesions that conform to a territorial distribution are the sequelae of embolic strokes. Cerebral angiography should be performed in all children with septic emboli. It delineates the occluded artery and may demonstrate mycotic aneurysm.

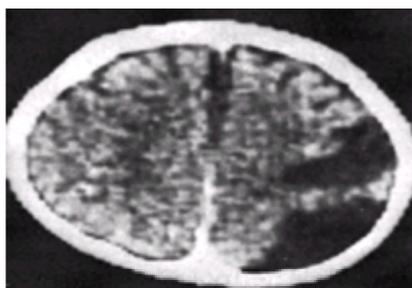

FIG. 43.6. Cerebral embolism. Computed tomography 3 months after cerebral embolism shows multiple infarcts. Sharp margins have density of CSF.

Treatment

Management of cerebral embolism is primarily symptomatic, including anticonvulsants for seizures. Anticoagulants are rarely used in children. Corticosteroids, in dosages used in the management of cerebral edema, are effective in reversing the pulmonary symptoms of fat embolism.

INTRACRANIAL HEMORRHAGE

Hemorrhagic stroke in children usually results from trauma or bleeding disorders. When these conditions are excluded, intracranial hemorrhage is caused by an arteriovenous malformation or aneurysm.

Signs and Symptoms

The child with subarachnoid hemorrhage usually presents with acute onset of headache, vomiting, stupor or coma, and convulsions. Findings include stiff neck and Brudzinski and Kernig signs. Extensor plantar responses and subhyaloid hemorrhages on funduscopic examination are often noted early. Fever and systemic hypertension are nonspecific findings. Ruptured cerebral aneurysm frequently presents with a catastrophic clinical picture. Bleeding from an arteriovenous malformation is less dramatic and is often associated with focal signs.

Laboratory Data

Blood dyscrasias are identified by appropriate blood studies. Children with bleeding from other causes have polymorphonuclear leukocytosis, normal or moderately elevated ESR, and transient albuminuria and glycosuria.

CSF analysis and CT document subarachnoid hemorrhage. Sonography in the infant with an open fontanel and CT at any age are invaluable in the diagnosis of intracranial hemorrhage and its complications. CT may demonstrate arteriovenous malformation ([Fig. 43.7](#)) or giant cerebral arterial aneurysm. Cerebral angiography is the definitive diagnostic technique for these conditions.

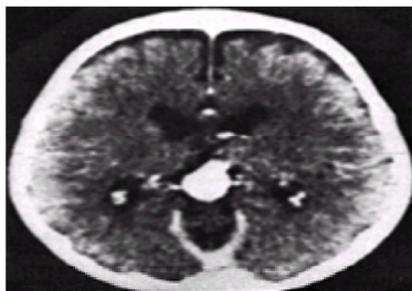

FIG. 43.7. Arteriovenous malformation. Computed tomography shows aneurysmal dilatation of vein of Galen due to large deep malformation. Note enlargement of draining sinuses and mild hydrocephalus with ventricular enlargement.

Treatment

The management of intracranial hemorrhage varies with the cause of the hemorrhage. Repeated lumbar punctures, mannitol, and corticosteroids are often used, but their effectiveness is controversial. Ruptured intracranial aneurysms require good nursing care, and unless the child is comatose or there is a medical contraindication, surgical extirpation offers the best prognosis. Except in cases of mycotic aneurysms, the occurrence of a second hemorrhage shortly after the initial hemorrhage is uncommon in children. Arteriovenous malformations should be surgically removed whenever possible. Embolization may be used preoperatively to reduce the size of the malformation or to treat inaccessible lesions. Traumatic arteriovenous fistulas are treated by ligation of the fistula, embolization, or the implantation of detachable balloons.

METABOLIC DISORDERS

MELAS is a mitochondrial disorder associated with two identifiable mitochondrial DNA mutations. MELAS is characterized by four criteria: a strokelike episode before age 40 years; encephalopathy characterized by seizures, dementia, or both; lactic acidosis; and ragged red fibers in the muscle biopsy ([Chap. 96](#)). Some patients with MELAS have features of other mitochondrial disorders.

Homocystinuria (cystathionine synthetase deficiency) is an autosomal recessive inherited disorder featuring elevated serum methionine and homocystine concentrations and excessive urinary excretion of homocystine. Cerebral arterial occlusive disease and venous thrombosis occur in this condition.

Medical therapies for stroke are designed to (1) minimize or prevent ischemic brain infarction, (2) optimize functional recovery, and (3) avert stroke recurrence. Specific therapies depend on the stroke syndrome, as discussed in this chapter.

Atherothrombotic brain infarction (ABI) and artery-to-artery thromboembolic strokes are the most common stroke syndromes and result from atherosclerosis. ABI represents a continuum from transient ischemic attacks (TIAs) to completed strokes with fixed neurologic deficits. Intermediate manifestations of ABI are progressing strokes or strokes in evolution.

TRANSIENT ISCHEMIC ATTACKS

TIAs are brief attacks of neurologic symptoms in either the carotid or vertebrobasilar circulations. In attacks involving the carotid circulation, focal neurologic symptoms develop, such as amaurosis fugax or transient monocular blindness, hemiparesis, or aphasia; in the vertebrobasilar circulation, symptoms are more generalized, such as visual blurring, vertigo, ataxia, dysarthria, and diplopia. TIAs usually last for minutes to hours, but by convention symptoms and signs may persist for up to 24 hours. TIAs usually result from platelet aggregates forming on atheromatous plaques and embolizing to temporarily occlude a distal arteriole. The resulting ischemic symptoms of brain or retina correspond to the arteriole temporarily rendered ischemic. Because hemodynamic factors can cause similar symptoms of ischemia due to reduced cerebral or retinal blood flow and by compressive brain lesions, transient neurologic symptoms alone cannot definitively identify the underlying cause or pathology. For example, these symptoms may occur with emboli of cardiac origin, thrombocytosis, polycythemia vera, arteritis, or, rarely, mass lesions (e.g., meningioma and subdural hematoma) or seizures.

With vertebrobasilar TIAs or vertebrobasilar insufficiency, these symptoms may be simulated by hemodynamic causes of reduced blood flow, such as decreased cardiac output. Because cardiac arrhythmias may be etiologic, Holter monitoring may be required to establish a diagnosis.

For patients with carotid TIAs and greater than 70% carotid bifurcation stenosis, carotid endarterectomy (CEA), performed by demonstrably skilled surgeons, is the treatment of choice in medically suitable patients. Three prospective, randomized studies assessing the value of CEA in these patients were published in 1991, and each demonstrated the benefits of CEA. The three studies were the North American Symptomatic Carotid Endarterectomy Trial (NASCET), the MRC European Carotid Surgery Trial, and the Veterans Affairs Cooperative Study on Carotid Endarterectomy. In 1998, preliminary results of NASCET showed a 6.5% reduction in strokes following CEA in patients with 50% to 69% stenosis; there was no reduction in strokes for those with less than 50% stenosis. Because the actual cost-benefit of CEA is controversial, as is the use of CEA in asymptomatic subjects, clinicians must make their decisions on the basis of whether the stenosis is progressing, on factors related to operative risk, and on stroke-risk factors.

Extracranial–intracranial bypass surgery, or the anastomosis of the superficial temporal artery to the middle cerebral artery, does not prevent further strokes following TIAs or minor strokes in patients with inaccessible stenoses or occlusions in the carotid artery territory. However, this procedure may be beneficial in patients with hemodynamic causes of TIAs, although this has not been proven. A new and promising area of therapy is balloon angioplasty and stenting for both extracranial and intracranial occlusive disease. Although a steep learning curve indicates that experience conveys improved outcome, aggregate results are encouraging. For example, a review of over 2,000 cases of carotid angioplasty and stenting showed a success rate of nearly 98%, with death and stroke rates of approximately 2%. Despite these encouraging outcomes, it is too early to declare this procedure a standard. Nonetheless, for patients with occlusive disease who are not surgical candidates, angioplasty offers a reasonable alternative.

To prevent recurrence, medical therapy of TIAs or minor strokes due to occlusive vascular disease includes an anticoagulant and antiplatelet drugs such as aspirin, ticlopidine, clopidogrel, or dipyridamole in combination with aspirin. Aspirin reduces the incidence of stroke by about 25%, as determined by a large metaanalysis. The most effective dose of aspirin, whether ultralow at 30 to 75 mg per day or large at 1,300 mg per day, is controversial and will require a prospective study to resolve. Until those studies are undertaken, one or two adult aspirin tablets daily can be recommended, since this dose has less bleeding complications. Ticlopidine is more effective than aspirin, particularly in the elderly (greater than 75 years) and women, as well as for vertebrobasilar symptoms, small-vessel disease of brain, and aspirin failure. This drug is ineffective with high-grade carotid stenosis (greater than 70%). Clopidogrel, an analog of ticlopidine, has fewer side effects such as diarrhea, bruising, and leukopenia that require monitoring over the first several months of use, as with ticlopidine. The combination of dipyridamole and aspirin is controversial because of the design of the study in which it was tried, but certain patients may benefit. Short-term subcutaneous heparin does not avert stroke as effectively as aspirin according to the International Stroke Trial with nearly 20,000 subjects worldwide. Furthermore, the low-molecular-weight heparin study showed no benefit with this therapy. The value of aspirin was also demonstrated in the Chinese Acute Stroke Trial with over 20,000 patients. Anticoagulation with warfarin sodium (Coumadin) appears to reduce stroke recurrence with intracranial arterial stenoses, as shown in a retrospective study, but the true value of this treatment will await the prospective study. Until the results of that study, however, anticoagulation can be recommended in suitable patients with an international normalized ratio (INR) between 2.0 and 3.0.

PROGRESSING STROKES

A gradual or stuttering increase in neurologic deficits over hours suggests the diagnosis of progressing stroke, provided mass lesions (e.g., hematoma or edema) have been excluded. The progressive symptoms are attributed to an enlarging intraarterial thrombus.

Although thrombolytic agents such as alteplase (tissue plasminogen activator [t-PA]) or urokinase have not been systematically investigated under these circumstances, thrombolysis should be considered if the National Institutes of Health (NIH) guidelines (reviewed below) are met. However, in the posterior circulation, some authorities recommend intraarterial, catheter-delivered thrombolysis, even in patients who are stuporous and whose symptoms have progress beyond 12 hours. The objective benefits of this therapy will require prospective, randomized studies.

COMPLETED STROKES WITH FIXED NEUROLOGIC DEFICITS

The approach to acute ischemic stroke has been dramatically and convincingly altered since t-PA was shown to significantly improve neurologic recovery, provided treatment begins within 3 hours of stroke onset and computed tomography (CT) of the brain is normal or shows only minimal infarction. The protocol approved by the U.S. Food and Drug Administration and NIH for t-PA use is shown in [Table 44.1](#). Despite approval of this guideline, controversy exists on the use of t-PA, particularly if specialized stroke units and teams are not available.

Duration	<3 h from onset
CT brain	No hemorrhage or clear infarction
Laboratory studies	Hematocrit, platelets, PT/PTT
If above are negative or normal, treat with intravenous tPA	
Administer tPA, 0.9 mg/kg: 10% in 1 min; remainder in 60 min	
Perform hourly neurologic examinations x 6, then every 2 h for first 24 h	
Repeat CT and blood studies at day 2	

TABLE 44.1. THROMBOLYSIS WITH TPA IN ACUTE ISCHEMIC STROKE

Similar benefits with t-PA were shown in the European Cooperative Acute Stroke Study when protocol violators were excluded. This same group in Europe will try to replicate the NIH study, and in North America, use of t-PA in the 3- to 5-hour poststroke period was being assessed, but the trial has been put on hold. In European and Australian studies of streptokinase, increased incidence of hemorrhage caused early termination of the trials.

The success with thrombolysis further stimulated the use of so-called neuroprotective agents to minimize ischemic brain damage resulting from both increased release of excitotoxins (e.g., glutamic acid) during ischemia and oxidative and other injuries during reperfusion with recanalization. Although experimental studies demonstrated the value of these agents, particularly those that blocked or inhibited the excitotoxins, calcium uptake, adhesion molecules, and free radical formation, clinical trials of these compounds have been disappointing. These include Λ -methyl-D-aspartate (NMDA) receptor blockers such as selfotel, aptiganel (Cerestat), and MK-801; the glutamate secretion inhibitor lubeluzole; and the anti-ICAM (intercellular adhesion molecule) monoclonal antibody enlimomab. However, other compounds such as clomethiazole, citicoline, and still others show promise but must await further prospective studies.

Another area of current investigation is the use of mechanical devices either to physically extract or suction out the thrombus. These corkscrew, laser, or suction devices are promising, but it is too early to determine their proper clinical role.

EMBOLIC STROKE OF CARDIAC AND AORTIC ORIGIN

Therapy of cardiac emboli depends on the cardiac pathology: An infected prosthetic valve may require replacement, and myxomatous emboli necessitate surgical excision of the tumor. The most common cause (more than 50%) of embolic stroke of cardiac origin is atrial fibrillation with or without mitral pathology and recent myocardial infarction. Postinfarction emboli are likely to follow large anterior or septal infarcts or infarcts with akinetic segments detected by two-dimensional echocardiography. Before age 45 years, mitral valve prolapse may be a cause, but primarily in those with leaflet redundancy.

For emboli associated with atrial fibrillation or myocardial infarction, anticoagulation to reduce reembolization is warranted. In the Stroke Prevention in Atrial Fibrillation (SPAF) study, anticoagulation substantially reduced embolic stroke regardless of the subject's age, even after age 75 years. An increased incidence of embolization with atrial fibrillation was associated with the following factors: previous embolic strokes, left ventricular hypertrophy with reduced ejection fraction, hypertension, and congestive failure. Having no risk factors was associated with a 1.5% to 2.5% per year incidence of stroke, while two or more risk factors raised the incidence to more than 17%.

One common cardiac anatomic abnormality causing embolic stroke is patent foramen ovale (PFO). Implicating PFO as the cause of stroke requires certain criteria: absence of a likely cause of stroke, demonstration of right-to-left shunting (as shown by transthoracic echocardiography following intravenous saline bubbles), evidence of straining at the onset of the stroke (which raises intrathoracic pressure), and a PFO of sufficient size (e.g., greater than 2 mm in diameter). Although prospective studies on the treatment of PFO have not been performed, it is reasonable to treat symptomatic patients initially with aspirin or anticoagulation. However, recurrent stroke symptoms require either percutaneous, catheter-delivered clamshell closure or open heart surgery with foraminal closure, which is the more definitive option.

A newly recognized cause of embolic stroke is aortic atheromas. Significant atheromas measure greater than 4 mm in diameter and are usually not calcified. Whether anticoagulation will reduce emboli will be the subject of an international prospective study.

Anticoagulation is not recommended if an infarct is large either by CT or clinical signs. Lumbar puncture is unnecessary to exclude hemorrhage if CT studies are adequate.

INTRACEREBRAL HEMORRHAGE

Medical treatment of intracerebral hemorrhage is supportive. For large cerebellar hemorrhages, as with sizable infarcts, surgical decompression is required if vital structures of the medulla are at risk, as suggested by fourth ventricle displacement, lateral ventricular enlargement, cisternal obliteration, and declining levels of consciousness. Surgical evacuation of a hematoma is considered for lobar or cortical white matter hemorrhages if there are signs of declining sensorium or herniation in an operatively suitable candidate. However, ongoing studies should clarify precise criteria for surgery of polar or white matter hemorrhages. Surgery is not beneficial for hemorrhages in the other common sites, such as putamen, thalamus, and pons. Lumbar puncture in the presence of intracerebral hemorrhage may precipitate herniation and is contraindicated.

SUBARACHNOID HEMORRHAGE WITH CONGENITAL OR BERRY ANEURYSM

Surgical, balloon, or coagulative extirpation of an aneurysm is definitive therapy in subarachnoid hemorrhage (SAH). After SAH, sedation and a quiet environment are essential to prevent marked elevation of arterial pressure that may provoke rebleeding, a major complication of SAH. Use of antifibrinolytic agents to prevent rebleeding by preserving the thrombus around the bleeding site has not been successful. A second complication of SAH is vasospasm, which correlates with the amount of blood in the subarachnoid space. Nimodipine, a calcium channel blocker, has been shown in prospective, randomized studies to avert vasospasm or at least ischemic complications. A third complication is hydrocephalus due to the obstructive nature of subarachnoid blood to cerebrospinal fluid flow, and ventricular shunting may be required to relieve pressure. Other, less common complications that may require intervention include seizures, the syndrome of inappropriate antidiuretic hormone secretion, and cardiac arrhythmias.

STROKE REHABILITATION

Physical rehabilitative measures should begin as soon as possible after stroke onset to maximize functional recovery. These measures are directed toward improvement in activities of daily living, muscle strength, ambulation, transfer, dressing, and hygiene, as well as toward avoidance of contractures and psychologic factors such as depression and motivation. Depression can occur in cerebral lesions of both hemispheres and may respond well to antidepressants such as the tricyclics and the serotonin-reuptake inhibitors. Speech and occupational therapies should be utilized to optimize rehabilitation.

STROKE PREVENTION

Stroke prevention is directed to the underlying pathologic processes such as atherosclerosis, arteritis, cardiac disease, dissection, and so on.

Atherothrombotic Brain Infarction

Treatment of hypertension is the most powerful preventive measure to avoid ABI and has resulted in a greater than 25% reduction in stroke incidence over the last several decades. Control of hypertension also reduces stroke recurrence; the optimum blood pressure, as determined by an international study, is approximately

145/85 mm Hg. In African-American subjects, the optimum blood pressure control may be lower, at approximately 115 mm Hg systolic. Measures to intervene aggressively against other risk factors for atherosclerosis should be undertaken. These include tight (but not excessive) control of blood glucose in diabetics, dietary and drug control of blood cholesterol, and reduction of smoking, obesity, stress, and sedentary lifestyles. The total cholesterol level should be less than 240 mg/dL, but preferably less than 200 mg/dL; and the low-density lipoprotein fraction should be less than 130 mg/dL, preferably near 100 to 110 mg/dL. A metaanalysis of all forms of treatment aimed at reducing cholesterol following myocardial infarction, namely, a diet low in cholesterol and saturated fats, fibric acid derivatives, resins, and HMG-CoA reductase inhibitors (statins) show that statins are the most effective in both reducing cholesterol and preventing myocardial infarction and stroke. Whether or not statins prevent recurrent stroke following ABI has not been studied, but a statin is a reasonable therapeutic option if the cholesterol is elevated and cost is not an issue.

Prophylactic use of aspirin to prevent stroke in asymptomatic persons, based on the rationale of its benefit in TIA patients with extracranial occlusive disease, is controversial. A few studies suggest an increased incidence of hemorrhagic stroke in asymptomatic elderly individuals. However, until a definitive prospective, randomized study is performed, one adult aspirin tablet daily can be recommended, since the benefit of preventing myocardial infarction appears to outweigh the risk of stroke.

CHAPTER 45. SUBARACHNOID HEMORRHAGE

STEPHAN A. MAYER, GARY L. BERNARDINI, JOHN C.M. BRUST AND ROBERT A. SOLOMON

[Pathology and Epidemiology of Intracranial Aneurysms](#)
[Clinical Manifestations](#)
[Diagnostic Studies](#)
[Complications of Aneurysmal Subarachnoid Hemorrhage](#)
[Treatment of Aneurysmal Subarachnoid Hemorrhage](#)
[Other Kinds of Macroscopic Aneurysms](#)
[Suggested Readings](#)

Subarachnoid hemorrhage (SAH) accounts for 5% of all strokes; it affects nearly 30,000 individuals per year in the United States, with an annual incidence of 1 per 10,000. Saccular (or berry) aneurysms at the base of the brain cause 80% of all cases of SAH. Nonaneurysmal causes of SAH are listed in [Table 45.1](#). SAH most frequently occurs between ages 40 and 60 years, and women are affected more often than men.

Trauma
Idiopathic perimesencephalic SAH
Arteriovenous malformation
Intracranial arterial dissection
Cocaine and amphetamine use
Mycotic aneurysm
Pituitary apoplexy
Moyamoya disease
Central nervous system vasculitis
Sickle cell disease
Coagulation disorders
Primary or metastatic neoplasm

TABLE 45.1. NONANEURYSMAL CAUSES OF SAH

SAH due to the rupture of an intracranial aneurysm is a devastating event; approximately 12% of patients die before receiving medical attention, and another 20% die after admission to the hospital. Of the two-thirds of patients who survive, approximately one-half remain permanently disabled, primarily due to severe cognitive deficits. Advances in neurosurgery and intensive care, including an emphasis on early aneurysm clipping and aggressive therapy for vasospasm, have led to improved survival over the last three decades, with a reduction in overall case fatality from approximately 50% to 33%.

PATHOLOGY AND EPIDEMIOLOGY OF INTRACRANIAL ANEURYSMS

Saccular aneurysms most often occur at the circle of Willis or its major branches, especially at bifurcations. They arise where the arterial elastic lamina and tunica media are defective, and tend to enlarge with age. The typical aneurysm wall is composed only of intima and adventitia and can become paper-thin. Many aneurysms, particularly those that rupture, are irregular and multilobulated, and larger aneurysms may be partially or completely filled with an organized clot, which occasionally is calcified. The point of rupture is usually through the dome of the aneurysm.

Eighty-five to ninety percent of intracranial aneurysms are located in the anterior circulation, with the three most common sites being the junction of the posterior communicating and internal carotid artery (approximately 40%), the anterior communicating artery complex (approximately 30%), and the middle cerebral artery at the first major branch point in the sylvian fissure (approximately 20%). Posterior circulation aneurysms most often occur at the apex of the basilar artery or at the junction of the vertebral and posteroinferior cerebellar artery. Saccular aneurysms of the distal cerebral arterial tree are rare. Nearly 20% of patients have two or more aneurysms; many of these are “mirror” aneurysms on the same vessel contralaterally.

Intracranial aneurysms are uncommon in children but occur with a frequency of 2% in adults, suggesting that approximately 2 to 3 million Americans have an aneurysm. However, more than 90% of these are small (less than 10 mm) and remain asymptomatic throughout life.

The annual risk of rupture of an asymptomatic intracranial aneurysm is approximately 0.7%. By contrast, the annual risk of bleeding of a previously ruptured aneurysm after 6 months is substantially higher, between 2% and 4% per year.

The prevalence of aneurysms increases with age and is higher in patients with atherosclerosis, a family history of intracranial aneurysm, or autosomal-dominant polycystic kidney disease (PCKD). Intracranial aneurysms have also been associated with Ehlers-Danlos syndrome, Marfan syndrome, pseudoxanthoma elasticum, coarctation of the aorta, and sickle-cell disease. Screening for unruptured intracranial aneurysms with magnetic resonance angiography (MRA) is indicated in patients with PCKD and in family members who have two or more first-degree relatives with intracranial aneurysms; testing will be positive in 5% to 10% of these individuals.

Among patients who harbor an intracranial aneurysm, the strongest risk factors for bleeding are previous rupture, large size, and cigarette smoking. The risk of SAH is approximately five times higher for aneurysms greater than 10 mm in diameter than for smaller aneurysms, and 3 to 10 times higher among smokers than nonsmokers. Other risk factors for aneurysm rupture include hypertension, alcohol use, female sex, posterior circulation location, multiple aneurysms, and cocaine or amphetamine use.

CLINICAL MANIFESTATIONS

SAH usually commences with an explosive “thunderclap” headache followed by neck stiffness. The pain is often described as “the worst headache of my life.” The headache is usually generalized, but focal pain may refer to the site of aneurysmal rupture (e.g., periorbital pain related to an ophthalmic artery aneurysm). Common associated symptoms include loss of consciousness, nausea and vomiting, back or leg pain, and photophobia. In patients who lose consciousness, tonic posturing may occur and may be difficult to differentiate from a seizure. Although aneurysmal rupture often occurs during periods of exercise or physical stress, SAH can occur at any time, including sleep.

More than one-third of patients give a history of suspicious symptoms days or weeks earlier, including headache, stiff neck, nausea and vomiting, syncope, or disturbed vision. These prodromal symptoms are often due to minor leaking of blood from the aneurysm, and are therefore referred to as “warning leaks” or “sentinel headaches.” In 25% of patients, the initial manifestations of SAH are misdiagnosed, which can lead to delays in treatment and increased morbidity and mortality.

Neck stiffness and the Kernig sign are hallmarks of SAH. However, these signs are not invariably present, and low back pain is sometimes more prominent than headache. Preretinal or subhyaloid hemorrhages—large, smooth-bordered, and on the retinal surface—occur in up to 25% of patients and are practically pathognomonic of SAH.

The most important *determinant* of outcome after SAH is the patient's neurologic condition on arrival at the hospital. Alterations in mental status are the most common abnormality; some patients remain alert and lucid; others are confused, delirious, amnesic, lethargic, stuporous, or comatose. The modified Hunt and Hess grading scale serves as a means for risk stratification for SAH based on the first neurologic examination ([Table 45.2](#)). Patients classified as grade I or II SAH have a relatively good prognosis, grade III carries an intermediate prognosis, and grades IV and V have a poor prognosis. Focal neurologic signs occur in a minority of patients but may point to the site of bleeding; hemiparesis or aphasia suggests a middle cerebral artery aneurysm, and paraparesis or abulia suggests an aneurysm of the

proximal anterior cerebral artery. These focal signs are sometimes due to a large focal hematoma, which may require emergency evacuation.

Grade	Clinical Findings	Hospital Mortality (%)	
		1968	1997
I	Asymptomatic or mild headache	11	1
II	Moderate to severe headache or oculomotor palsy	26	5
III	Confused, drowsy, or mild focal signs	37	19
IV	Stupor (localizes to pain)	71	42
V	Coma (posturing or no motor response to pain)	100	77
Total		35	18

Data from 275 patients reported by Hunt and Hess in 1968, and 214 patients reported by Oshiro et al. 1997; mortality figures do not include out-of-hospital deaths. (Modified from Tamargo RJ, Walter KA, Oshiro EM. Aneurysmal subarachnoid hemorrhage: prognostic features and outcomes. *New Horiz* 1997, 5:364-375.)

TABLE 45.2. HUNT AND HESS GRADING SCALE FOR ANEURYSMAL SAH

In 10% of patients with nontraumatic SAH and in two-thirds of those with negative angiography, computed tomography (CT) reveals blood confined to the perimesencephalic cisterns, with the center of bleeding adjacent to the midbrain and pons. These patients with “perimesencephalic” SAH always have a normal neurologic examination and a benign clinical course; sentinel headaches, rebleeding and vasospasm almost never occur. The source of hemorrhage in these patients is unknown but is presumably venous.

Symptoms and signs of an unruptured intracranial aneurysm may result from compression of adjacent neural structures or thromboembolism. These aneurysms are often, but not always, large or giant (greater than 25 mm). Aneurysms of the posterior communicating artery frequently compress the oculomotor nerve (almost always affecting the pupil). Aneurysms of the intracavernous segment of the internal carotid artery may damage the third, fourth, fifth, or sixth cranial nerves, and their rupture can lead to formation of a carotid cavernous fistula. Less often, large aneurysms compress the cortex or brainstem, causing focal neurologic signs or seizures. Thrombosis within the aneurysmal sac occasionally sends emboli to the artery's distal territory, causing transient ischemic attacks or infarction. In the absence of SAH, some patients experience sudden, severe headache without nuchal rigidity, perhaps related to aneurysmal enlargement, thrombosis, or meningeal irritation; these symptoms can clear with aneurysm clipping.

DIAGNOSTIC STUDIES

Computed Tomography

CT should be the first diagnostic study for establishing the diagnosis of SAH. CT most commonly demonstrates diffuse blood in the basal cisterns (Fig. 45.1); with more severe hemorrhages, blood extends into the sylvian and interhemispheric fissures, ventricular system, and over the convexities. The distribution of blood can provide important clues regarding the location of the ruptured aneurysm. CT may also demonstrate a focal intraparenchymal or subdural hemorrhage, ventricular enlargement, a large thrombosed aneurysm, or infarction due to vasospasm. The sensitivity of CT for SAH is 90% to 95% within 24 hours, 80% at 3 days, and 50% at 1 week. Accordingly, a normal CT never rules out SAH, and a lumbar puncture should always be performed in patients with suspected SAH and negative CT. Magnetic resonance imaging (MRI) is most useful for evaluating patients with amniogram-negative SAH.

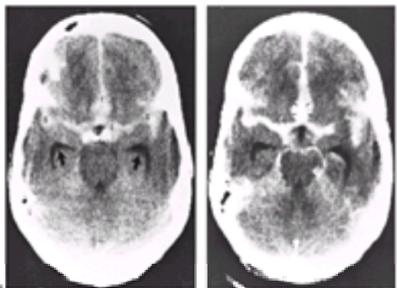

FIG. 45.1. A: Noncontrast CT demonstrates hyperdensity within the suprasellar cistern (C) and interhemispheric fissure (F). Note the hyperdensity of subarachnoid blood within both sylvian fissures (S). There is prominence of both temporal horns, indicative of mild communicating hydrocephalus. **B:** Contrast CT demonstrates enhancement of an anterior communicating artery aneurysm observed within the interhemispheric fissure (arrows). (Courtesy of Dr. Richard S. Pinto.)

Lumbar Puncture

The cerebrospinal fluid (CSF) is usually grossly bloody. SAH can be differentiated from a traumatic tap by a xanthochromic (yellow-tinged) appearance of the centrifuged supernatant; however, xanthochromia may take up to 12 hours to appear. CSF pressure is nearly always high and the protein elevated. Initially, the proportion of CSF leukocytes to erythrocytes is that of the peripheral blood, with a usual ratio of 1:700; after several days a reactive pleocytosis and low glucose levels may develop due to a sterile chemical meningitis caused by the blood. Red blood cells and xanthochromia disappear in about 2 weeks, unless hemorrhage recurs.

Angiography

Cerebral angiography is the definitive diagnostic procedure for detecting intracranial aneurysms and defining their anatomy (Fig. 45.2). Because there is often more than one aneurysm, the entire cerebral arterial system must be studied. Vasospasm, local thrombosis, or poor technique can lead to a false-negative angiogram. For this reason, patients with a negative angiogram at first should have a follow-up study 1 to 2 weeks later; an aneurysm will be demonstrated in about 5% of these cases. The exception to this rule is patients with “perimesencephalic” SAH, who usually do not require follow-up angiography. At present, neither MRA nor CT angiography is sensitive enough to serve as the diagnostic test of choice for detecting intracranial aneurysms.

communicating artery. (Courtesy Dr. S. Chan.)

COMPLICATIONS OF ANEURYSMAL SUBARACHNOID HEMORRHAGE

Rebleeding

Aneurysmal rebleeding is a dreaded complication of SAH. The risk of rebleeding is highest within the first 24 hours after the initial aneurysmal rupture (4%), and remains elevated (approximately 1% to 2% per day) for the next 4 weeks (Fig. 45.3). The cumulative risk of rebleeding in untreated patients is 20% at 2 weeks, 30% at 1 month, and 40% at 6 months. After the first 6 months, the risk of rebleeding is 2% to 4% annually. The prognosis of patients who rebleed is poor; approximately 50% die immediately, while another 30% die from subsequent complications. Although rebleeding is often attributed to uncontrolled hypertension, endogenous fibrinolysis of clot around the rupture point of the aneurysm may be a more important causative mechanism.

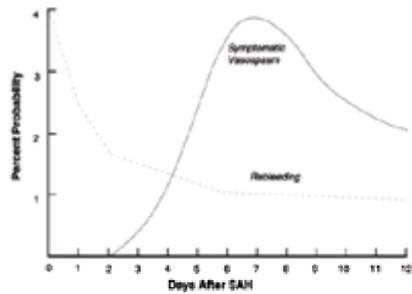

FIG. 45.3. The daily percentage probability for the development of symptomatic vasospasm (solid line) or rebleeding (dashed line) after SAH. Day 0 denotes day of onset of SAH.

Vasospasm

Delayed cerebral ischemia from vasospasm accounts for a large proportion of morbidity and mortality after SAH. Progressive arterial narrowing develops after SAH in approximately 70% of patients, but delayed ischemic deficits develop in only 20% to 30%. The process begins 3 to 5 days after the hemorrhage, becomes maximal at 5 to 14 days, and gradually resolves over 2 to 4 weeks. Accordingly, deterioration attributable to vasospasm never occurs before the third day after SAH, and occurs with peak frequency between 5 and 7 days (see Fig. 45.3). There is a strong relationship between the amount of cisternal blood seen on initial CT and the risk for the development of symptomatic ischemia. Symptoms usually include a change in level of consciousness, focal neurologic signs (e.g., hemiparesis), or both, and the process is usually most severe in the immediate vicinity of the aneurysm.

Although thick subarachnoid blood is the principal precipitating factor, the precise cause of arterial narrowing after SAH is poorly understood. Vasospasm is not simply due to vascular smooth muscle contraction; arteriopathic changes are seen in the vessel wall, including subintimal edema and infiltration of leukocytes. The prevailing view is that substances released from the blood clot interact with the vessel wall to cause inflammatory arterial spasm. Putative mediators include oxyhemoglobin (with its intrinsic vasoconstrictive properties), hydroperoxides and leukotrienes, free radicals, prostaglandins, thromboxane A₂, serotonin, endothelin, platelet-derived growth factor, and other inflammatory mediators.

Hydrocephalus

Acute hydrocephalus occurs in 15% to 20% of patients with SAH and is primarily related to the volume of intraventricular and subarachnoid blood. In mild cases, hydrocephalus causes lethargy, psychomotor slowing, and impaired short-term memory. Additional findings may include limitation of upward gaze, sixth cranial nerve palsies, and lower extremity hyperreflexia. In more severe cases, acute obstructive hydrocephalus leads to elevated intracranial pressure. Affected patients are stuporous or comatose, and progressive brainstem herniation eventually results from continued CSF production unless a ventricular catheter is inserted.

Delayed hydrocephalus may develop from 3 to 21 days after SAH. The clinical syndrome is identical to that of normal pressure hydrocephalus, with insidious onset of dementia, gait disturbance, and urinary incontinence. The clinical response to ventriculoperitoneal shunting is usually excellent. Overall, 20% of SAH patients require shunting for chronic hydrocephalus.

Seizures

Seizures occur in 5% to 10% of SAH patients. Two-thirds of seizures occur within the first month, and the remainder occur within the first year. Seizures after SAH are related primarily to large amounts of subarachnoid or parenchymal clot. Ictal events at the onset of bleeding do not portend an increased risk of late seizures.

Fluid and Electrolyte Disturbances

Hyponatremia and intravascular volume contraction frequently occur after SAH and reflect homeostatic derangements that favor excessive free-water retention and sodium loss. Hyponatremia occurs in 5% to 30% of patients after SAH and is primarily related to inappropriate secretion of antidiuretic hormone and free-water retention. This process may be further exacerbated by excessive natriuresis that occurs after SAH ("cerebral salt-wasting"), related to elevations of atrial natriuretic factor and the glomerular filtration rate. Whereas hyponatremia after SAH is usually mild and asymptomatic, sodium loss and intravascular volume contraction increase the risk of ischemia in the presence of severe vasospasm. To minimize the development of hypovolemia and hyponatremia after SAH, patients should be given large volumes of isotonic crystalloid, with restriction of other potential sources of free water.

Neurogenic Cardiac and Pulmonary Disturbances

Severe SAH is typically associated with a surge in catecholamine levels and sympathetic tone, which in turn can lead to neurogenic cardiac dysfunction, neurogenic pulmonary edema, or both. Transient electrocardiographic abnormalities occur in at least 50% of patients with SAH but usually do not produce symptoms. In some poor-grade patients, however, cardiac enzyme release and a reversible form of neurogenic "stunned myocardium" can occur. Hypotension and reduction of cardiac output may result, leading to impaired cerebral perfusion in the face of increased intracranial pressure or vasospasm. Neurogenic pulmonary edema, characterized by increased permeability of the pulmonary vasculature, may occur in isolation or in combination with neurogenic cardiac injury.

TREATMENT OF ANEURYSMAL SUBARACHNOID HEMORRHAGE

The initial goal of treatment is to prevent rebleeding by excluding the aneurysmal sac from the intracranial circulation while preserving the parent artery and its branches. Once the aneurysm has been secured, the focus shifts toward monitoring and treating vasospasm and other secondary complications of SAH. This is best performed in an intensive care unit (ICU).

Surgical Management

Surgical clipping is the definitive treatment for aneurysms. In the 1980s, neurosurgeons began to abandon the traditional practice of delaying surgery until several

weeks after aneurysmal rupture, in favor of early clipping within 48 to 72 hours. This change in practice became feasible with safer microsurgical techniques. Nonetheless, surgery still remains hazardous, with a 5% to 10% risk of major morbidity or mortality in most cases. Besides preventing early rebleeding, early surgery permits aggressive treatment of vasospasm with hypertensive hypervolemic therapy, which can be dangerous with an unclipped aneurysm. Although early surgery was first reserved for patients in good clinical condition (Hunt and Hess grades I to III), this approach has been extended to all but the most moribund patients. The advent of endovascular coil embolization has been a major advance because it is a treatment option for high-risk patients who are not good candidates for early surgery.

Very large aneurysms of the basilar artery, long deemed untreatable, can now be clipped in specialized centers that provide deep hypothermic circulatory arrest. This technique gives the surgeon the necessary exposure to identify and preserve penetrating arteries that supply the brainstem. Good neurologic outcomes can be attained in more than 80% of patients, despite total circulatory arrest for 20 to 40 minutes.

The management of asymptomatic unruptured aneurysms is controversial. Most neurosurgeons recommend surgery for aneurysms larger than 5 mm, as long as the potential benefit of surgery (reduced lifetime risk of bleeding) outweighs the risks. In good hands, the risk of major morbidity or mortality from clipping of an unruptured aneurysm is 2% to 5%; the risk is highest for large aneurysms and for aneurysms of the basilar artery.

Endovascular Therapy

Endovascular therapy, introduced in the early 1990s, is a promising alternative for the treatment of aneurysms that are not amenable to surgical repair. Endovascular packing of aneurysms (Fig. 45.4) with soft, thrombogenic detachable platinum coils leads to at least short-term obliteration of small-necked aneurysms in 80% to 90% of cases, with an acceptable complication rate of approximately 9%. Aneurysms with wider necks are less amenable to treatment because it is more difficult to attain complete obliteration and the coils or thrombus may migrate. The main disadvantage of endovascular treatment is the potential for rebleeding after many years due to coil compaction and aneurysm regrowth at the residual neck. Until long-term follow-up studies define this risk more precisely, long-term serial angiography is recommended for patients with intracranial aneurysms treated with coils.

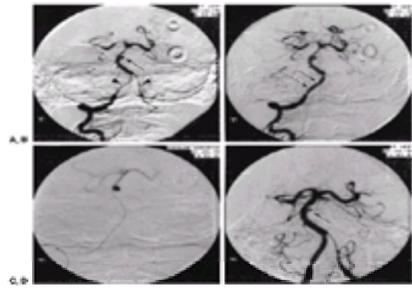

FIG. 45.4. A: Cerebral angiogram demonstrates a left-pointing, 3-mm, midbasilar aneurysm (*closed arrow*) and vasospasm of both vertebral arteries (*open arrows*), the distal basilar artery, and the proximal right posterior cerebral artery. **B:** Significant increase in luminal diameter of the right vertebral artery after balloon angioplasty (*arrows*). **C:** Microcatheter positioned at the neck of the midbasilar aneurysm. **D:** Midbasilar aneurysm (*arrow*) with no residual filling after packing with a single platinum detachable coil. (Courtesy of Dr. Huang Duong.)

Large, expanding aneurysms of the intracavernous internal carotid artery can be treated with proximal endovascular occlusion. Before permanent occlusion, a trial balloon occlusion is performed to determine whether there is adequate collateral flow through the circle of Willis to prevent symptomatic ischemia in the ipsilateral hemisphere. If the test occlusion is negative, an extracranial–intracranial bypass procedure may be considered before permanent occlusion is attempted.

Intensive Care Management

A suggested algorithm for the postoperative management of SAH is outlined in Table 45.3. All patients with SAH should be monitored in an ICU, where neurologic examinations can be performed frequently. Although the efficacy of blood pressure reduction in preventing early rebleeding has not been established, it seems prudent to maintain systolic pressure at 150 mm Hg or less until the aneurysm has been secured. Similarly, a loading dose of an intravenous anticonvulsant, such as fosphenytoin, is given to prevent early rebleeding related to seizures, although this risk is small. Anticonvulsants may be discontinued on the second postoperative day if the patient has not had a seizure.

Blood pressure	Control elevated blood pressure (BP) during the postoperative phase (systolic BP >150 mm Hg) with intravenous labetalol or nicardipine to prevent rebleeding.
Hemodynamic stabilization	Preoperative normotensive (BP) values at 80–120 mm Hg. Postoperative normotensive (BP) values at 80–120 mm Hg, and 20–30 mm Hg diastolic every 15 min. Postoperative normotensive (BP) values at 80–120 mm Hg, and 20–30 mm Hg diastolic every 15 min if the patient remains normotensive (BP) in primary artery (systolic pressure >150 mm Hg).
Labetalol therapy	For labetalol, rapid control blood pressure (BP) for treatment of severe hypertension (SBP >180 mm Hg) in patients with symptomatic hypertension. For labetalol, check electrolytes to detect hypokalemia. Obtain an ECG, and check laboratory studies (systolic BP >180 mm Hg) to evaluate for cardiac injury, perform echocardiography if a patient with abnormal ECG findings.
Systemic prophylaxis	Fosphenytoin or phenytoin (15–20 mg/kg) (systolic BP >150 mm Hg) in patients with a seizure.
Neuroleptic analgesia	Remediate, if necessary, every 4 h for 2–4 days. Transcranial Doppler (TCD) monitoring every 1–2 days until day 8–10 after SAH.
Therapy for symptomatic hydrocephalus	Place patient in Trendelenburg head-down position. Obtain CT scan, if necessary, every 12–24 hours. If the patient remains normotensive (BP >150 mm Hg) with phenylephrine or dopamine until the BP is stable, up to a maximum of 220 mm Hg. Continue "high-dose" hypertensive protocol (see primary artery catheter, and add labetalol to maintain systolic BP <150 mm Hg). Emergency angiogram for possible rebleeding (if the patient has a severe deficit, e.g., hemiparesis) or rebleeding (if the patient has a severe deficit, e.g., hemiparesis) or rebleeding (if the patient has a severe deficit, e.g., hemiparesis).

TABLE 45.3. COLUMBIA-PRESBYTERIAN MANAGEMENT PROTOCOL FOR ACUTE SAH

Most centers advocate the use of prophylactic volume expansion with isotonic crystalloid (with or without additional colloids) to prevent volume contraction, although this has not been proven to reduce the risk of symptomatic ischemia from vasospasm. A central venous or pulmonary artery catheter is used in high-risk patients to guide fluid administration on the basis of target cardiac filling pressures. The calcium channel blocker nimodipine has been shown to reduce the frequency of delayed ischemic deterioration by approximately 30% in several clinical trials; this effect is presumably mediated by reduction of calcium entry into ischemic neurons or by improvement in microcollateral flow, since no effect on angiographic spasm was demonstrated.

Use of dexamethasone in acute SAH is controversial; it is often used in the perioperative period for brain relaxation. There is no specific evidence to suggest that it is beneficial, although it may reduce the headache sometimes associated with vasospasm. Externalized ventricular drains are used to treat obstructive hydrocephalus in patients who are stuporous or comatose, but these devices carry a high risk of infection (15% overall) that increases beyond 5 days. Serial lumbar puncture is used to treat hydrocephalus in patients who are following commands.

Transcranial Doppler ultrasonography is widely used to diagnose vasospasm of the larger cerebral arteries after SAH. Accelerated blood flow velocities, which occur as flow is maintained through narrowed arteries, have a sensitivity and specificity of 90% for angiographic vasospasm of the proximal middle cerebral artery, but they are less sensitive for detecting spasm of the anterior cerebral or basilar arteries.

Treatment of acute symptomatic vasospasm relies on increasing blood volume, blood pressure, and cardiac output in an attempt to improve cerebral blood flow through arteries in spasm that have lost the capacity to autoregulate. Crystalloid or colloid solutions are given to maintain pulmonary artery diastolic pressure greater than 14 mm Hg or central venous pressure greater than 8 mm Hg. Pressors such as dopamine and phenylephrine are used to elevate systolic blood pressure to levels

as high as 180 to 220 mm Hg. Hypertensive-hypervolemic hemodilution (“triple-H therapy”) of this type results in clinical improvement in about 70% of patients; cerebral angioplasty can lead to dramatic improvement in patients with severe deficits that are refractory to hemodynamic augmentation (see [Fig. 45.4](#)).

Outcome after Subarachnoid Hemorrhage

In contrast to the severe physical handicaps that follow ischemic stroke, survivors of SAH are disabled primarily by cognitive impairment. Neuropsychologic testing reveals long-term problems in memory, concentration, psychomotor speed, visuospatial skills, or executive function in 60% to 80% of SAH patients. Depression and anxiety are also common. These disturbances do not lead to the outward appearance of disability but can affect work, relationships, and quality of life; about 50% of SAH patients do not return to their previous level of employment. Cognitive and physical rehabilitation are essential for maximizing recovery in severely affected patients.

OTHER KINDS OF MACROSCOPIC ANEURYSMS

Fusiform or Dolichoectatic Aneurysms

These circumferential vessel dilatations usually involve the carotid, basilar, or vertebral arteries. Atherosclerosis probably plays a role in their formation, but a developmental defect of the wall may be present in some. Fusiform aneurysms seldom become occluded with thrombus and rarely rupture. If bleeding occurs, treatment often requires proximal vessel occlusion.

Mycotic Aneurysm

Mycotic aneurysms are caused by septic emboli, which are most often formed by bacterial endocarditis. They are usually only a few millimeters in size and tend to occur on distal branches of pial vessels, especially those of the middle cerebral artery. Mycotic aneurysms have been reported in up to 10% of endocarditis patients, but arteriography is not routinely performed, and the incidence is probably underestimated. Pyogenic segmental arteritis from septic emboli in the absence of frank aneurysm formation can also lead to intracranial hemorrhage. Because rupture is fatal in 80% of patients with mycotic aneurysms, cerebral arteriography should be performed when endocarditis is accompanied by suspicious headaches, stiff neck, seizure, focal neurologic symptoms, or CSF pleocytosis. Although mycotic aneurysms occasionally disappear radiographically with antimicrobial therapy, the outcome cannot be predicted, and the aneurysm should be treated surgically as soon as possible.

Pseudoaneurysm

Dissection of an intracranial vessel, which usually results from trauma, can lead to extension of blood from the false lumen through the entire vessel wall. The extravasated blood is contained by either a thin layer of adventitia or the surrounding tissues and does not have a true aneurysmal wall, hence the designation *pseudoaneurysm*. If a vessel traversing the subarachnoid space is affected, SAH can result. Treatment may require endovascular or surgical vessel occlusion or trapping, or angioplasty and stenting of the involved segment.

Vascular (Arteriovenous) Malformations

Vascular malformations account for less than 5% of all cases of SAH. Intracranial and spinal vascular malformations can be classified into five main types: (1) arteriovenous malformations (AVMs), which are high-flow and most often symptomatic; (2) cavernous malformations; (3) capillary telangiectasias; (4) venous malformations; and (5) mixed malformations. More than 90% of vascular malformations are asymptomatic throughout life. Bleeding may occur in patients at any age but is most likely to occur in patients younger than 40 years. They are occasionally familial, and in 7% to 10% of cases AVMs coexist with saccular aneurysms.

AVMs are a conglomerate of abnormal arteries and veins with intervening gliotic brain tissue; they resemble a “bag of worms.” When bleeding from an AVM occurs, reported initial mortality has ranged from 4% to 20%. Early rebleeding is far less likely than after aneurysm rupture, but recurrent hemorrhage occurs in 8% to 18% of patients annually over the next several years. For patients without hemorrhage, the risk of bleeding is 2% to 4% per year. Besides prior hemorrhage, reported risk factors for bleeding from an AVM include deep venous drainage, small size, a single draining vein, high feeding-artery pressure, male sex, and a diffuse nidus.

The diagnosis of an AVM is made by MRI and arteriography. Small or thrombosed AVMs, especially in the brainstem, are occasionally missed by arteriography but detected by MRI, which better demonstrates the relationship of the malformation to surrounding brain and identifies its nidus. MRI is the preferred screening procedure for detecting vascular malformations; if surgery is contemplated, conventional angiography is required to delineate the vascular supply. Dural and spinal cord AVM should be kept in mind in patients with radiographically unexplained SAH.

Treatment depends on the location of the AVM and the age and condition of the patient. Direct surgical resection, endovascular glue embolization, and directed-beam radiation therapy with a linear accelerator or gamma-knife are the main treatment modalities. The long-term value of these treatments is unclear. Embolization is most useful for shrinking the malformation before surgery or radiation; it is occasionally curative as a single mode of therapy.

CHAPTER 46. CEREBRAL VEINS AND SINUSES

ROBERT A. FISHMAN

[Lateral Sinus Thrombosis](#)
[Cavernous Sinus Thrombosis](#)
[Superior Sagittal Sinus Thrombosis](#)
[Thrombosis of Other Dural Sinuses](#)
[Dural Arteriovenous Malformations](#)
[Suggested Readings](#)

Occlusion of the cerebral veins and sinuses occurs owing to thrombus, thrombophlebitis, or tumors. Occlusion of the cortical and subcortical veins may cause focal neurologic symptoms and signs. The dural sinuses that are most frequently thrombosed are the lateral, cavernous, and superior sagittal sinuses. Less frequently affected are the straight sinus and the vein of Galen. Factors predisposing to thrombosis and associated disorders include the following:

Primary idiopathic thrombosis

Secondary thrombosis

Pregnancy

Postpartum

Birth control pills

Trauma—after open or closed head injury

Tumors

Meningioma

Metastatic tumors

Malnutrition and dehydration (marantic thrombosis)

Infection—sinus thrombophlebitis, bacterial, fungal

Hematologic disorders

Polycythemia

Cryofibrinogenemia

Sickle-cell anemia

Leukemia

Disseminated intravascular coagulation and other coagulopathies

Behçet syndrome

LATERAL SINUS THROMBOSIS

Thrombosis of the lateral sinus is usually secondary to otitis media and mastoiditis. Infants and children are most commonly affected. Thrombosis may be coincident with the acute attack of otitis and mastoiditis, or it may occur in the chronic stage of infection.

Symptoms and Signs

Onset is usually heralded by fever and chills; however, fever may be absent. Septicemia most commonly occurs with hemolytic streptococci and is present in about 50% of patients. Petechiae in the skin and mucous membranes and septic embolism of the lungs, joints, and muscles are infrequent complications of the septicemia.

The classic symptoms of lateral sinus thrombosis are fever, headache, and nausea and vomiting. The latter signs are due to increased intracranial pressure and are most apt to occur when the right sinus is occluded; in most individuals, the right sinus drains the greater portion of blood from the brain. Local signs of thrombosis of the sinus are usually absent, but occasionally there is swelling over the mastoid region with distention of the superficial veins and tenderness over the jugular vein in the neck.

Papilledema develops in about 50% of patients. It is usually bilateral but is occasionally only on one side, possibly the result of asymmetric extension of the process to the cavernous sinuses. Increased intracranial pressure may cause separation of the sutures or bulging of the fontanelles in infants.

Drowsiness and coma are not uncommon symptoms. Convulsive seizures may also occur. Jacksonian seizures followed by hemiplegia may reflect extension of infection into the veins draining the hemispheres. These signs, however, often indicate a brain abscess. Diplopia may result from injury to the sixth cranial nerve by increased intracranial pressure or from involvement of the nerve by extension of the infection in the petrous bone. The combination of sixth nerve palsy (lateral rectus weakness) and pain in the face as the result of damage to the fifth nerve is the Gradenigo syndrome. There may be signs of damage to the ninth, tenth, and eleventh cranial nerves. These are attributed to pressure on these nerves by the distended jugular vein, as they pass through the jugular foramen. It seems more probable that they are caused by extension of the infection into the bone (osteomyelitis) surrounding these structures.

Laboratory Data

Leukocytosis is present in the blood, and the organism may be recovered from the blood in 50% of cases. The cerebrospinal fluid (CSF) shows the changes characteristic of an aseptic meningeal reaction. The pressure is increased. The fluid is usually slightly turbid or cloudy and contains several to many hundred leukocytes per cubic millimeter. The glucose content of the fluid is normal, and cultures are sterile, unless bacterial meningitis has developed.

Diagnosis

The diagnosis of lateral sinus thrombosis is usually made, based on signs of increased intracranial pressure in a patient with an acute or chronic otitis and mastoiditis. The development of a hemiplegia, aphasia, or hemianopia favors the possibility of an intracerebral abscess, which should be excluded with imaging studies.

Course and Prognosis

The mortality rate is high in untreated lateral sinus thrombosis. Occasionally, the infected thrombus may heal by complete organization, but more commonly death results from septicemia, meningitis, extension of the infection to the cavernous or longitudinal sinus, or abscess of the brain. When patients recover, intracranial pressure may continue to be elevated for some months, especially if the jugular vein on the right side is ligated.

Treatment

The occurrence of a thrombosis of the lateral sinus should be prevented by the prompt treatment of infections of the middle ear. Treatment of a thrombosis involves antibiotics and surgical drainage. Infected bone should be removed, the sinus should be exposed and drained, and the jugular vein should be ligated if necessary. Nonseptic patients may be candidates for thrombolytic therapy.

CAVERNOUS SINUS THROMBOSIS

Cavernous sinus thrombosis usually originates in suppurative processes of the orbit, nasal sinuses, or upper one-half of the face. The infection commonly involves only one sinus at the onset but rapidly spreads through the circular sinus to the opposite side. One or both sides may be secondarily involved by extension of infection from the other dural sinuses. Nonseptic thrombosis of the cavernous sinus is rare. The sinus may be partially or totally occluded by tumor masses, trauma, or

arteriovenous aneurysms.

Symptoms and Signs

The onset of a septic thrombosis is usually sudden and dramatic. The patient appears acutely ill, and there is a septic type of fever. There is pain in the eyes, and the orbits are painful to pressure. The globes are proptosed by orbital edema and chemosis of the conjunctivae and eyelids. Diplopia follows involvement of the oculomotor nerves. Ptosis may be present and obscured by the exophthalmos. The optic discs are swollen, and there are numerous small or large hemorrhages around the disc when the orbital veins are occluded. The corneas are cloudy and ulcers may develop. The pupils may be dilated or small. Pupillary reactions may be lost. Visual acuity may be normal or moderately impaired. The laboratory findings in patients with cavernous sinus thrombosis are similar to those in patients with lateral sinus thrombosis.

Diagnosis

Cavernous sinus thrombosis must be distinguished from other conditions that produce exophthalmos and congestion in the orbit. These include orbital tumors, meningiomas and other tumors in the region of the sphenoid, malignant exophthalmos, and arteriovenous fistulas. The evolution of symptoms is slow in the latter conditions, except arteriovenous fistulas. These can be differentiated by the presence of pulsating exophthalmos and an orbital bruit, and recession of the exophthalmos when the carotid artery is occluded by digital pressure. Computed tomography (CT), magnetic resonance imaging (MRI), and MR venography (MRV) are valuable in establishing the diagnosis.

Treatment

Septic thrombosis of the cavernous sinus was once almost invariably fatal because of the development of an acute meningitis. Cures now are possible with appropriate antibiotics, with or without anticoagulation.

SUPERIOR SAGITTAL SINUS THROMBOSIS

The superior sagittal sinus is less commonly the site of an infective thrombosis than either the lateral or cavernous sinuses. Infections may reach the superior sagittal sinus from the nasal cavities or as secondary extensions from the lateral or cavernous sinuses. The superior sagittal sinus may also be occluded by extension of infection from osteomyelitis or from epidural or subdural infection.

The superior sagittal sinus is the most common site of nonseptic sinus thrombosis associated with dehydration and marasmus in infancy. It may also be occluded by trauma or by tumors (meningiomas). Sagittal sinus thrombosis has also been associated with oral contraceptive use, pregnancy, hemolytic anemia, sickle-cell trait, thrombocytopenia, ulcerative colitis, diabetes mellitus, Behçet syndrome, and other diseases. Nonseptic thrombosis of the sinus occasionally occurs in adults without any known cause.

Symptoms and Signs

The general signs are prostration, fever, headache, and papilledema. Local signs include edema of the forehead and anterior part of the scalp and engorgement of the veins in the area of the anterior or posterior fontanelles, with the formation of a caput medusae. Focal neurologic signs and symptoms may be entirely absent in nonseptic thrombosis, with increased intracranial pressure as the only presenting sign. However, extension of the clot into the larger cerebral veins is almost always accompanied by the onset of dramatic signs caused by hemorrhage into the cortical white and gray matter. Extension into these veins is common in septic thrombosis and in a high percentage of the nonseptic type. Convulsive seizures (often unilateral), hemiplegia, aphasia, or hemianopia may occur. The diagnosis of nonseptic thrombosis should be considered in all infants who show signs of increased intracranial pressure and cerebral symptoms during the course of severe nutritional disturbances and cachexia.

The laboratory findings with septic thrombosis of the superior sagittal sinus are similar to those in patients with lateral sinus thrombosis. Occasionally, the CSF is bloody or xanthochromic as the result of cortical and meningeal hemorrhage.

Diagnosis

The diagnosis can be established by radiography or MR angiography. CT and MRV may show multiple, often bilateral lesions, some hemorrhagic and others radiolucent (Fig. 46.1 and Fig. 46.2). The *cord sign* is a linear area of increased density that is related to clot in veins or sinus. The *empty delta sign* appears after injection of contrast material, which outlines the periphery of the sinus where blood still flows, leaving the central area of the clot dark; there may also be enhancement of the gyri or tentorium. Ventricles may be large or small. Cerebral angiography is definitive, showing the venous block or collateral flow. MRV, a noninvasive procedure, may graphically demonstrate the occlusion.

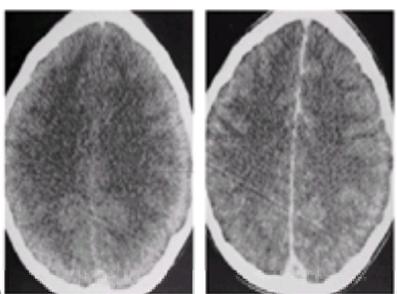

FIG. 46.1. Sinus thrombosis, hemorrhagic venous infarction. **A:** Axial CT without contrast enhancement demonstrates density in the sagittal sinus posteriorly. **B:** At the same level postcontrast, the empty delta sign is noted in the affected sinus. Thrombus density caused a central filling defect within the sinus. Triangular enhancement at the periphery is related to collateral venous channels within the dura. (Courtesy of Drs. S.K. Hilal and J.A. Bello.)

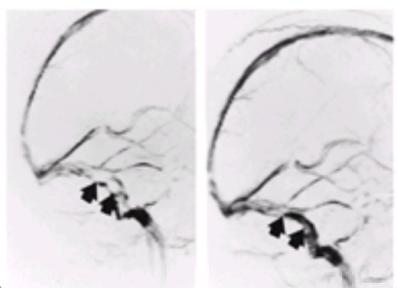

FIG. 46.2. A 34-year-old man with bilateral papilledema, increasing headache, and blurred vision. Routine spin-echo MR image was normal. **A:** Two-dimensional time-of-flight (TOF) MRV at time of symptoms shows filling defects at the junction of right transverse and sigmoid sinuses (arrows). **B:** Two-dimensional TOF MRV after local infusion of urokinase shows near-total resolution of filling defects (arrows). The patient's symptoms were markedly improved. (Courtesy of Drs. Phillip Baum

and David Norman.)

Prognosis

The prognosis is guarded in patients with a septic thrombosis. Death may result from meningitis or hemorrhagic lesions in the brain. Survivors may have focal neurologic deficits and recurrent convulsive seizures. The prognosis is less grave in patients with nonseptic thrombosis. Symptoms may recede several months after recanalization of the sinus or development of collateral circulation.

Treatment

Antibiotics should be administered to patients with septic thrombosis. Craniotomy with evacuation of subdural or epidural abscess should be performed when these are present. Heparin or thrombolytic therapy has been beneficial in some patients despite the risks of hemorrhagic infarction. Acetazolamide may be useful in lowering intracranial pressure. The role of steroids has not been established.

THROMBOSIS OF OTHER DURAL SINUSES

Thrombosis of the inferior longitudinal sinus, the straight sinus, the petrosals, or the vein of Galen rarely occurs alone. These sites are usually involved by secondary extension of a septic or nonseptic thrombosis of the lateral, superior sagittal, or cavernous sinuses. Any signs or symptoms that may be produced by thrombosis of the inferior longitudinal, straight, or petrosal sinuses are usually masked by those resulting from involvement of the more important sinuses. Thrombosis of the great vein of Galen may cause hemorrhages in the central white matter of the hemispheres or in the basal ganglia and lateral ventricles.

DURAL ARTERIOVENOUS MALFORMATIONS

Dural arteriovenous malformations (AVMs) are more common in women than men, and occur more often in the posterior fossa than above the tentorium. They may cause peripheral cranial nerve involvement (most commonly, third, seventh, eighth, and twelfth) or central nervous system manifestations. The latter are attributed to intracranial venous hypertension, decreased CSF absorption, venous sinus thrombosis, or minimal subarachnoid bleeding. Seizures, motor weakness, and brainstem and cerebellar syndromes have been observed, depending on the region involved. Some patients experience subarachnoid hemorrhaging or papilledema and headache only, as in idiopathic pseudotumor. Diagnosis usually requires detailed cerebral angiography, including selective injection of the external carotid and both vertebral arteries. Therapy with selective embolization using silicone or other agents may be beneficial and may require direct surgical excision. Spontaneous thrombosis of a dural AVM with remission of symptoms is not unusual; many lesions have a benign prognosis. Dural AVMs also occur in the spinal cord, often presenting as an insidiously progressive paraparesis.

CHAPTER 47. VASCULAR DISEASE OF THE SPINAL CORD

LEON A. WEISBERG

[Infarction of the Spinal Cord](#)
[Venous Disease](#)
[Spinal Cord Hemorrhage](#)
[Suggested Readings](#)

Blood supply to the spinal cord and nerve roots originates in the vertebral, thyrocervical, costocervical, intercostal, and lumbar arteries, which give rise to radicular and medullary arteries. The segmental radicular arteries supply the nerve roots, originating near the vertebral foramina. Six to nine large medullary arteries originate from the vertebral, subclavian, or iliac arteries and the aorta ([Fig. 47.1](#)). Branches of the medullary arteries form a single anterior median spinal artery and two posterior spinal arteries, which perfuse the spinal cord. The anterior median spinal artery arises from the vertebral artery, and it runs along the entire length of the cord. The pial arteriolar plexus and posterior spinal arteries supply the dorsal aspect of the cord.

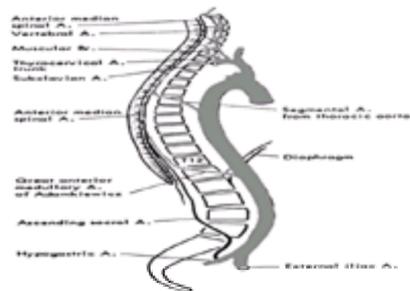

FIG. 47.1. The anterior median spinal artery is joined at various levels by arteries arising from the vertebral and subclavian arteries, the aorta, and the iliac arteries.

In the cervical region, the anterior median artery is collateralized at several levels by unpaired medullary arteries derived from the vertebral and subclavian arteries; this blood supply is rich in collateral branches. In the thoracic region, the anterior median spinal artery is joined by only a few branches of the thoracic aorta, and blood supply is relatively sparse, especially in the lower segments. The midthoracic spinal cord is supplied by terminal vessels descending from the subclavian and vertebral arteries or ascending from the abdominal aorta; this watershed is particularly vulnerable to vascular insufficiency, and spinal cord infarction is most likely to occur at T-4 to T-9. Because of its relative hypovascularity, the midthoracic region is particularly vulnerable to effects of hypotensive infarction. Midthoracic spinal syndrome (e.g., T-4 myelopathy) may be “false localizing,” and apparent clinical dysfunction at this level may actually be due to impaired perfusion at higher or lower cord levels or to global ischemia. Lumbar and sacral spinal areas are supplied by the largest and most constant of medullary arteries, the “great anterior radicular artery” of Adamkiewicz. This is usually found at L-1 or L-2 (occasionally as high as T-12 or as low as L-4). This artery, paired or single, travels through the vertebral foramen and anastomoses with the anterior medial spinal artery; the largest branch supplies the lumbosacral spinal cord and conus medullaris. Conus and cauda equina are also supplied by sacral branches ascending from the iliac arteries.

The central (sulcal) arteries originate in the anterior spinal artery to supply the anterior two-thirds and central area of the spinal cord. Penetrating branches from the pial arterial plexus supply the periphery and posterior one-third of the cord. Within the spinal cord, these arterial feeders anastomose in their most distal parts, creating border zones similar to those in the brain. These vascular border zones may explain the development of incomplete or partial syndromes seen after some spinal cord infarctions (see [Fig. 47.1](#)).

The plexiform venous system interconnects freely with the radicular arteries within subarachnoid space. The radicular veins empty into the epidural venous plexus, which in turn communicates with the inferior vena cava and azygos system through the perivertebral plexus.

INFARCTION OF THE SPINAL CORD

Softening or infarction of the spinal cord (myelomalacia) results from occlusion of major vessels. Anterior spinal artery infarction is much more common than the posterior spinal artery syndrome because of the difference in collateral supply between these two regions.

Etiology

Spinal cord infarction is most often caused by atheromas involving the aorta and results as a potential complication of thoracoabdominal aneurysm repair. In one series, spinal infarction represented 1.2% of stroke admissions. Less common causes of spinal cord infarction include collagen vascular disease (including systemic lupus and polyarteritis), syphilitic angiitis, dissecting aortic aneurysm, embolic infarction (bacterial endocarditis, nucleus pulposus), pregnancy, sickle-cell disease, neurotoxic effects of iodinated contrast material used in angiography, compression of spinal arteries by tumor, systemic arterial hypotension as a consequence of cardiac arrest, and decompression sickness. Paraplegia may follow surgical repair of an aortic aneurysm when cross-clamp time is longer than 25 minutes; the risk of neurologic deficit may be lessened by avoiding systemic arterial hypotension, placing the shunt around the cross-clamp, and using thiopental anesthesia. Spinal cord ischemia may occur as an early complication of spinal arteriovenous malformation (AVM) repair (surgery, embolization).

Symptoms and Signs

The symptoms of spinal stroke usually appear within a few minutes or hours of the onset of ischemia. The first symptom may be local or radicular back pain. This may be lancinating or burning and is usually transient. There may also be diffuse, deep, aching pain in both legs, or a burning, dysesthetic pain may start in the feet and rapidly ascend to calves, thighs, and abdomen. These sensory symptoms are followed by rapid onset of leg weakness; the patient is soon unable to walk, reaching a peak of disability within minutes. Occlusion of the cervical part of the anterior spinal artery causes tetraplegia, incontinence of urine and feces, and sensory impairment below the level of the lesion. Proprioception and vibration sensations are spared because the posterior columns are supplied by the posterior arterial plexus. If proprioception and vibration sensation are impaired, the lesion is most likely not an anterior spinal artery infarction, and alternative diagnoses should be considered. Spastic weakness in the legs results from lesions of the lateral corticospinal tract. Sometimes, signs are restricted to those of either upper or lower motor neurons (or both) in a pattern similar to that of amyotrophic lateral sclerosis (ALS), but with major differences in mode of onset and lack of progressive worsening in spinal stroke. If the spinal ischemia involves only the gray matter supplied by sulcal arterial branches, there may be only lower motor neuron deficit (amyotrophy). The sudden onset of the motor deficit is consistent with a vascular etiology; however, if the deficit develops more slowly and progressively, clinical differentiation from ALS or spinal cord tumor may be difficult.

The level of the deficit in spinal ischemia may involve high-cervical or low-sacral regions, with the mean level of deficit occurring at T-8. Most clinical spinal cord strokes affect the midthoracic region, where paraplegia, urinary incontinence, and loss of pain and temperature sensation, with sparing of proprioception and vibration, localize the level. The weakness is flaccid at first, but Babinski signs are seen, and spasticity and hyperreflexia usually develop in a few weeks.

Arterial insufficiency of the lumbar region causes paraplegia, sphincter symptoms, and loss of cutaneous sensation with sacral sparing. The weakness is more likely to remain flaccid because the anterior horn cells are affected.

Transient ischemic attacks of the spinal cord and cauda equina may occur, but there is no way to confirm this clinical impression. These attacks may precede spinal

artery infarction, sometimes in association with lumbar spondylosis and stenosis. Symptoms may be precipitated by postural change in patients with lumbar stenosis. In cervical spondylosis, the role of arterial compression is uncertain in the subsequent development of myelopathy.

Diagnosis

Shadow spine radiography, myelography, computed tomography (CT), and magnetic resonance imaging (MRI) are needed to rule out spinal cord neoplasm or cervical spondylosis, which may simulate spinal cord stroke. Lumbar puncture excludes hemorrhagic or infectious disorders. In spinal cord infarction, cerebrospinal fluid (CSF) may show a slight protein content elevation, but gamma globulin content is normal. Two conditions that may simulate spinal infarction are multiple sclerosis (MS) and cord neoplasm. In MS or transverse myelitis, CSF frequently shows elevated gamma globulin content. Neoplasms are more likely to increase CSF protein content to values of several hundred milligrams per deciliter. In spinal cord infarction, myelography is usually normal; however, edema may cause signs of an intramedullary mass and subarachnoid block. Spinal angiography may cause cord infarction and is contraindicated unless spinal vascular malformation is considered likely. MRI may initially be normal in spinal ischemia but may later show focal swelling and abnormal (hyperintense) signal characteristics on T2-weighted sequences. Gadolinium-enhanced MRI would suggest an alternative etiology, such as MS, an infectious–inflammatory condition, neoplasm, vasculitis, or AVM. CT is unlikely to visualize an ischemic spinal lesion; however, it is likely to visualize spinal cord hemorrhage or vertebral abnormalities that may be the cause of the spinal syndrome.

Treatment and Prognosis

The general principles of care for patients with quadriplegia or paraplegia should be followed. Naloxone hydrochloride (Narcan) and calcium channel blockers have been used experimentally to treat spinal cord ischemia, but no studies have been undertaken in humans. There is no evidence to support utilization of antiplatelets or anticoagulants for spinal ischemia. The prognosis for recovery is varied. In one review, the following was reported: died (22%), unimproved (24%), minimally improved (9%), improved (25%), markedly improved (20%).

The major predisposing factor for spinal ischemia is surgical reconstruction of thoracoabdominal aortic aneurysm. The potential for spinal ischemia and resulting neurologic deficit depends on aneurysm extension and whether dissection has occurred. Despite utilization of hypothermia, intraoperative somatosensory monitoring, reanastomosis of intercostal arteries, short clamp time, distal aortic perfusion, and CSF drainage techniques, spinal ischemia is a potential risk of aortic aneurysm repair.

VENOUS DISEASE

Venous disorders of the spinal cord are even less common than arterial lesions. Venous infarction may occur in patients with sepsis, systemic malignancy, or spinal vascular malformation. Patients experience sudden back pain, and motor, sensory, and autonomic dysfunctions develop. Sensory impairment does not necessarily spare the posterior columns (as is characteristic of anterior spinal artery ischemia). CSF examination is necessary to exclude infectious–inflammatory or neoplastic conditions in patients with spinal cord ischemia. CT or MRI is necessary to exclude alternative lesions, including vascular malformations.

Foix-Alajouanine syndrome (subacute or progressive necrotic myelopathy) is characterized by spinal cord necrosis and evidence of enlarged, tortuous, thrombosed veins. Although this necrotic myelitis is attributed to venous thrombosis, there is usually no angiographic evidence of venous thrombosis or vascular spinal cord malformation. There is pathologic evidence of vascular malformations that are believed to have undergone spontaneous vascular thrombosis. There are multiple small infarcts and hemorrhagic spinal lesions. Pathologically, the necrosis for the most part involves the corticospinal tract, sparing anterior horn cells, and the lesion is most prominent in the thoracolumbar region. Clinically, there is usually subacute or progressive worsening of the condition for several weeks. The prodrome may include back or leg pain. Symptoms include leg weakness, incontinence, and sensory loss. Findings usually include spastic paraparesis, hyperreflexia, bilateral Babinski signs, and sensory level below the lesion. CSF may show a markedly elevated protein content, leukocytic pleocytosis, and red blood cells. Treatment with anticoagulants or corticosteroids has not been effective. Because some venous infarctions of the spinal cord are hemorrhagic, anticoagulation is potentially dangerous in this condition.

SPINAL CORD HEMORRHAGE

Hemorrhage in the spinal cord is rare and may be epidural, subdural, subarachnoid, or intramedullary in location. Hematomyelia (hemorrhage into the substance of the spinal cord) usually immediately follows a spinal injury; however, it may be delayed for hours or days. Nontraumatic causes of spinal cord hemorrhage include blood disorders (e.g., leukemia), anticoagulation therapy, AVM, or venous spinal cord infarction.

Pathology

In intramedullary spinal cord hemorrhage, the spinal cord is swollen because of an intramedullary central blood clot. The blood dissects longitudinally for several segments below and above the hemorrhage, most severely affecting the gray matter and contiguous white matter. The clot is usually surrounded by a rim of normal nervous tissue. With time, the blood is liquefied and removed by phagocytes. Glial replacement is usually incomplete, resulting in a syrinxlike cavity that extends over several cord segments.

Signs and Symptoms

Localized back or radicular pain is sudden in onset. If hemorrhage is small, there may be only spastic weakness associated with hyperreflexia in the legs and bladder dysfunction. If hemorrhage is large, signs of cord transection include flaccid paralysis, complete sensory loss below the lesion, absent reflexes, Babinski signs, and loss of sphincter control. Autonomic disturbance and vasomotor instability may result in cardiovascular shock. If the patient survives, the hematoma is reabsorbed and symptoms may improve, but outcome is uncertain. Spinal subdural or epidural hemorrhage is usually due to trauma (including lumbar puncture) or coagulopathy. Initially, patients experience neck or back pain and radiculopathy, or myelopathy may subsequently develop.

Diagnosis

CSF is bloody or xanthochromic (especially if there is an associated subarachnoid hemorrhage), and protein content is increased. Myelography shows evidence of an intradural intramedullary mass with subarachnoid block. CT shows the hyperdense hematoma more clearly than MRI. Spinal angiography may be indicated in nontraumatic cases if spinal vascular malformation is suspected.

Spinal epidural or subdural hemorrhage may cause mass effect that rapidly compresses the cord. This may follow spinal trauma, even without evidence of bone fracture; other causes include anticoagulation and blood dyscrasias, and there are cases without obvious etiology. Epidural hemorrhage may follow lumbar puncture in patients with a coagulation disorder. The symptoms of epidural and subdural spinal hematoma are similar. Symptoms of epidural hemorrhage appear rapidly, with back pain, sensory loss, and sphincter impairment. The diagnosis is established by CT, which directly visualizes the hemorrhage, or myelography, which shows evidence of cord compression by an extradural mass. Spinal subarachnoid hemorrhage may be due to vascular malformation, spinal neoplasm (most commonly ependymoma), blood dyscrasia, or periarteritis nodosa, which is characterized by sudden, severe back pain at the level of the lesion. Symptoms may be due to blood in the subarachnoid space or to blood dissecting into the spinal cord or along the nerve root sheaths. CSF is bloody and xanthochromic. CT shows the hyperdense hemorrhage. Myelography and spinal angiography are necessary to establish the cause. Ruptured intracranial aneurysm occasionally causes severe back pain with clinical findings indicative of spinal hemorrhage; in these cases, cerebral angiography may be necessary to determine the etiology, especially if the patient also reports headache and has nuchal rigidity.

Treatment

Treatment of spinal cord hemorrhage depends on the cause and location of the hemorrhage. For subdural and epidural hemorrhage, surgery is necessary, but the prognosis is poor when paraplegia is present and there is delay in surgical intervention. Patients with spinal cord hematomas caused by anticoagulant therapy should receive fresh whole blood and vitamin K. Spinal cord decompression is carried out if effective hemostasis can be achieved, but should be avoided if bleeding impairment is not correctable.

SECTION V. DISORDERS OF CEREBROSPINAL AND BRAIN FLUIDS

CHAPTER 48. HYDROCEPHALUS

LEON D. PROCKOP

[Obstructive Hydrocephalus](#)
[Communicating Hydrocephalus](#)
[Normal Pressure Hydrocephalus](#)
[Suggested Readings](#)

Hydrocephalus is characterized by increased cerebrospinal fluid (CSF) volume and dilation of the cerebral ventricles. It is classified according to the following types:

- Obstructive hydrocephalus
 - Congenital malformations
 - Postinflammatory or posthemorrhagic
 - Mass lesions
- Normal pressure hydrocephalus
- Communicating hydrocephalus
 - Overproduction of CSF
 - Defective absorption of CSF
 - Venous drainage insufficiency
- Hydrocephalus *ex vacuo*

When there are no clinical signs or symptoms of intracranial hypertension, hydrocephalus is *occult*. It is *active* when the disease is progressive, and there is increased intracranial pressure; hydrocephalus is *arrestea* when ventricular enlargement has ceased. Dandy and Blackfan introduced the terms *communicating* and *noncommunicating* hydrocephalus to describe the flow of CSF. They injected a tracer dye into one lateral ventricle. If the dye appeared in lumbar CSF, the hydrocephalus was termed *communicating*; if the dye did not appear in the lumbar CSF, the hydrocephalus was termed *noncommunicating*. This functional classification was widely accepted because it proved useful in surgical shunt placement; however, by this definition, noncommunicating hydrocephalus refers only to that caused by obstruction within the ventricular system. The term *obstructive hydrocephalus* is used to describe conditions after obstruction of either intraventricular or extraventricular pathways. In communicating hydrocephalus, no obstruction can be demonstrated by standard tests. *Normal pressure hydrocephalus* (NPH) warrants separate classification and discussion. These forms of hydrocephalus are distinguished from *hydrocephalus ex vacuo*, in which CSF volume increases without change in CSF pressure, because brain tissue has been lost (e.g., Alzheimer disease) ([Fig. 48.1](#)).

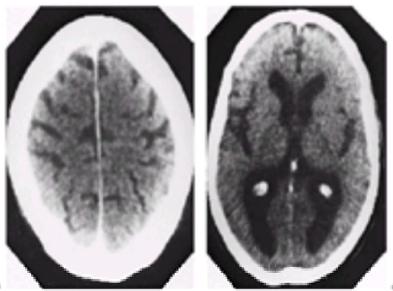

FIG. 48.1. Brain CT. Marked ventricular dilatation (A) and widening of cortical sulci (B) are indicative of hydrocephalus *ex vacuo* in a 64-year-old woman with dementia.

OBSTRUCTIVE HYDROCEPHALUS

Obstructive hydrocephalus is the best characterized and most common form of hydrocephalus. To facilitate clinical diagnosis and management, obstructive hydrocephalus is further classified as intraventricular obstructive hydrocephalus (IVOH) and extraventricular obstructive hydrocephalus (EVOH). In IVOH, the obstruction site determines proximal dilatation, with preservation of normal ventricular size distal to the block. Obstruction may occur at the foramen of Monro, the third ventricle, the aqueduct of Sylvius, the fourth ventricle, or the outflow of the foramina of Luschka and Magendie. In obstruction of extraventricular CSF pathways (EVOH), absolute or relative reduction of flow may occur in the subarachnoid spaces at the base of the brain, at the tentorial level, and over the hemispherical convexities. Because of the limitations of the clinical tests discussed later, the precise location of the obstruction or absorptive block cannot always be determined.

Obstructive hydrocephalus is caused by congenital malformations or developmental lesions, postinflammatory or posthemorrhagic fibrosis, or mass lesion.

Congenital Malformations or Developmental Lesions

Congenital hydrocephalus occurs with an incidence of 0.5 to 1.8 per 1,000 births and may result from either genetic or nongenetic causes. Common nongenetic causes include intrauterine infection, intracranial hemorrhage secondary to birth trauma or prematurity, and meningitis. Genetically, an X-linked hydrocephalus has been described. In most of these cases, aqueductal stenosis has been documented radiographically, by magnetic resonance imaging (MRI), or at postmortem examination. In some families, the occurrence of aqueductal stenosis, hydrocephalus of undetermined anatomic type, and the Dandy-Walker syndrome in siblings of both sexes has suggested alternate modes of inheritance. In the Dandy-Walker syndrome, there is expansion of the fourth ventricle and the posterior fossa, with obstruction of the foramina of Luschka and Magendie ([Fig. 48.2](#)). It is not clear whether aqueductal lesions (e.g., gliosis or fibrosis) occur developmentally or whether they are the residue of prior viral inflammatory disease contracted *in utero* or in early life ([Fig. 48.3](#)). The Arnold-Chiari malformation may be associated with hydrocephalus at birth, or it may develop later.

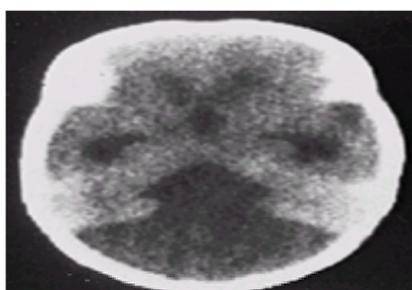

FIG. 48.2. Brain CT. Hydrocephalus associated with Dandy-Walker malformation in a 4-month-old child with increasing head circumference and bulging fontanelles.

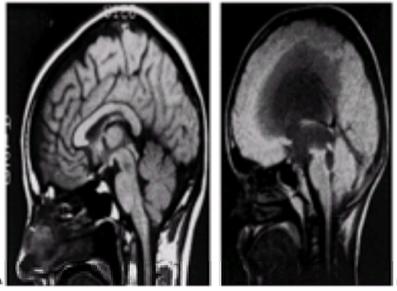

FIG. 48.3. A: Normal midsagittal brain anatomy demonstrated by T1-weighted MRI. **B:** On a similar scan of a child, abnormal membranous structures within the fourth ventricle and aqueduct of Sylvius caused dilation of the upper fourth, third, and lateral ventricles. (Courtesy of Dr. Reed Murtagh.)

Postinflammatory or Posthemorrhagic Hydrocephalus

Posthemorrhagic hydrocephalus is a major complication of cerebral intraventricular hemorrhage in low-birthweight infants, with an incidence 26% to 70%, depending on the severity of the hemorrhage. Hydrocephalus results from obstruction of CSF flow by a clot within the ventricular system or by obliterative basilar or transcortical arachnoiditis. After subarachnoid hemorrhage, the arachnoid villi are distended with packed red cells, suggesting an absorptive defect. Consequently, fibrotic impairment of extraventricular CSF pathways after intracranial hemorrhage may be complicated by dysfunction of arachnoid villi.

Likewise, intramedullary or intraventricular hemorrhage in adults causes hydrocephalus, especially if there are clots in the ventricles ([Fig. 48.4A](#)). Hydrocephalus also occurs in adults after subarachnoid bleeding owing to head trauma or aneurysmal rupture ([Fig. 48.4B](#)). In some patients, the obstruction of CSF flow is transient; intracranial pressure increases, and hydrocephalus appears but then disappears spontaneously. Other patients exhibit progressive hydrocephalus. This form of obstructive hydrocephalus is due to extraventricular obstruction to CSF flow and may be a form of, or may cause, NPH ([Fig. 48.5](#)).

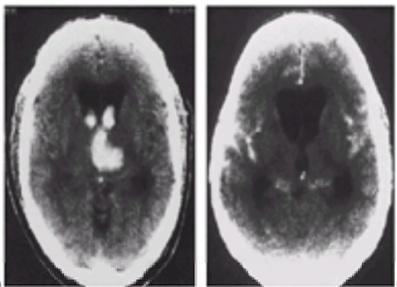

FIG. 48.4. A: Brain CT in a 58-year-old individual several hours after the sudden development of coma and right hemiparesis. Blood in the left thalamus and within the third and lateral ventricles is associated with hydrocephalus. **B:** Similar scan of adult 24 hours after the sudden onset of severe headache and meningism. Acute hydrocephalus with subarachnoid space blood is seen.

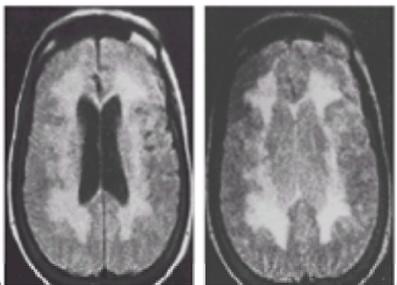

FIG. 48.5. A: Axial T1-weighted MR image of the brain shows lateral ventricular dilatation in a 42-year-old woman with dementia, ataxia, and urinary incontinence 3 months after subarachnoid hemorrhage. **B:** Axial, more T2-weighted image in this woman demonstrates periventricular increased signal intensity consistent with transependymal migration of CSF. Her condition improved after CSF shunting.

Among infectious diseases, tuberculous and luetic meningitis may cause hydrocephalus secondary to basal arachnoiditis. Computed tomography (CT) has demonstrated that hydrocephalus may also follow other forms of meningitis (e.g., bacterial, fungal, viral, carcinomatous) ([Fig. 48.6](#)).

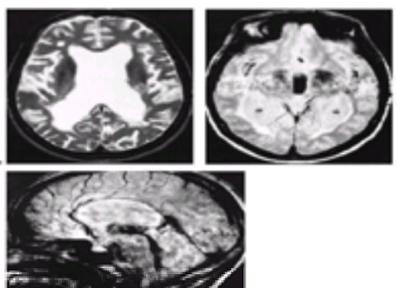

FIG. 48.6. Normal pressure hydrocephalus. A: Axial T2-weighted MR image shows dilated lateral ventricles with no evidence of sulcal effacement. **B,C:** Axial and sagittal proton-density MRI shows increased signal intensity around both lateral ventricles consistent with interstitial edema within the periventricular white matter. Pronounced flow void is seen within the third ventricle on the axial view; the sagittal view shows extension of the flow void down the aqueduct of Sylvius and into the fourth ventricle. This indicates abnormally increased CSF pulsations through these structures and may represent a prognostic marker for successful ventricular shunt placement for NPH. A ventricular shunt was placed, and this patient showed improvement in mental status and gait difficulty. (Courtesy of Dr. R. Muntagh.)

Mass Lesions

Intracranial neoplasms may cause obstructive hydrocephalus (Fig. 48.7). Other mass lesions, such as intraparenchymal cerebral hemorrhage and cerebellar infarction or hemorrhage, may lead to acute hydrocephalus. Basilar artery ectasia and other vascular abnormalities (e.g., vein of Galen malformation) have been associated with hydrocephalus.

FIG. 48.7. A: Midsagittal T1-weighted MR image in a 42-year-old woman demonstrates a pinealoma causing lateral ventricular dilation with a normal fourth ventricle. **B:** Axial T1-weighted imaging demonstrates the pineal region tumor and dilation of the proximal third and lateral ventricles.

COMMUNICATING HYDROCEPHALUS

When impairment of neither intraventricular nor extraventricular CSF flow can be documented, three other mechanisms may cause hydrocephalus: oversecretion of CSF, venous insufficiency, or impaired absorption of CSF by arachnoid villi.

When CSF *oversecretion* occurs, the absorptive capacity of the subarachnoid space is about three times the normal CSF formation rate of 0.35 mL per minute; formation rates greater than 1.0 mL per minute may produce hydrocephalus. Clinically, *choroid plexus papilloma* is the only known cause of oversecretion hydrocephalus.

Otitic hydrocephalus is a condition that occurs in children after chronic otitis media or mastoiditis with lateral sinus thrombosis; otherwise, impaired cerebral *venous drainage* (e.g., thrombosis of cortical veins or intracranial venous sinuses) rarely causes hydrocephalus. Hydrocephalus owing to extracranial venous drainage impairment only rarely follows radical neck dissection or obstruction of the superior vena cava.

Communicating hydrocephalus has been attributed to *congenital agenesis of the arachnoid villi* with consequent impairment of CSF absorption. Because detailed pathologic study of the number of villi and their structural characteristics is difficult and rarely performed, this defect may be more common than statistics indicate. Likewise, dysfunction of arachnoid villi without obstruction of basilar or transcortical CSF pathways cannot be assessed easily.

Hydrocephalus has also been described when CSF protein content exceeds 500 mg/dL in cases of polyneuritis or spinal cord tumor. The protein may interfere with CSF absorption. Ependymoma, the most common spinal cord tumor associated with hydrocephalus, may be due to tumor seeding of the arachnoid villi.

NORMAL PRESSURE HYDROCEPHALUS

As a potentially treatable cause of dementia, NPH has captured wide attention. The syndrome was first delineated in 1964 as an occult form of hydrocephalus. The absence of papilledema with normal CSF pressure at lumbar puncture led to the term *normal pressure hydrocephalus*; however, intracranial hypertension probably occurs before diagnosis. Intermittent intracranial hypertension has been noted during monitoring of suspected cases. Often, the syndrome follows head trauma, subarachnoid hemorrhage, or meningitis, or is associated with an occult mass lesion.

There is much speculation about the pathophysiology of NPH. Obliteration or insufficiency of the transcortical subarachnoid space may occur alone or with an impaired absorption defect at the arachnoid villi, leading to reduced conductance to CSF outflow.

General Clinical Data

Signs and Symptoms

In children before the cranial sutures fuse, hydrocephalus causes skull enlargement and widened fontanelles. The face, although of normal size, appears small relative to the enlarged head. Exophthalmos and scleral prominence result from downward displacement of the orbits. Severe intracranial hypertension produces sluggish pupillary reaction, absence of upward gaze, impaired lateral gaze, paralysis or spasm of convergence, nystagmus, retractions, and absence of visual fixation or response to visible threat. Untreated hydrocephalic infants fail to thrive and show retardation of motor and intellectual development. Limb movements, particularly of the legs, show progressive weakness and spasticity. Seizures are common. Prominent skull veins are evident, and a sound similar to that made by a cracked pot is noted on percussion. Wasting of trunk and limb muscles is apparent, with spasticity, increased tendon reflexes, and Babinski signs. With progression, the child is unable to lift the enlarged head. Visual loss is followed by optic atrophy. Scalp necrosis may lead to CSF leakage, infection, and death.

In otitic hydrocephalus, the child may be febrile and listless. Eardrum perforation and purulent otic discharge usually occur. Ipsilateral sixth nerve paralysis and papilledema are often noted.

In adults, symptoms include headache, lethargy, malaise, incoordination, and weakness. Seizures are uncommon. Findings may include dementia, altered consciousness, ocular nerve palsies, papilledema, ataxia, or corticospinal tract signs. Ventricular enlargement is not usually a uniform process and frequently occurs at the expense of periventricular white matter but with relative preservation of gray matter. Therefore, severe hydrocephalus may remain occult and, even though uncomplicated by brain tumor or other obvious causes, may be found by CT in adults with preserved mental state and signs limited to pyramidal tract or cerebellar dysfunction.

NPH is characterized by insidious onset and gradual development for weeks or months of the triad of dementia, ataxia of gait, and urinary incontinence. Headache and signs of increased intracranial pressure do not occur. Symptoms may begin weeks after head trauma or subarachnoid hemorrhage. In advanced disease, there may be frontal release signs, with hyperactive tendon reflexes and Babinski signs.

Laboratory Data

In infants, hydrocephalus must be distinguished from other forms of macrocephaly, such as subdural hematoma. Skull trans-illumination should be performed. Plain skull radiographs and skull measurements are useful to follow the course. Nonetheless, CT and MRI are the best diagnostic aids for all forms of hydrocephalus.

Lumbar puncture is sometimes indicated to measure CSF pressure and determine the presence of blood or signs of inflammatory or infectious disease. Continuous monitoring of intraventricular pressure may differentiate arrested from progressive disease when lumbar sac CSF pressure is normal and may not accurately reflect the intraventricular pressure. Likewise, CSF pulse-wave analysis may be more reliable than CSF pressure alone in diagnosis of hydrocephalus.

Ultrasonography is useful in evaluating subependymal and intraventricular hemorrhage in high-risk premature infants and in following the infants for possible later development of progressive hydrocephalus. Results correlate well with CT. As a bedside procedure, ultrasonography requires minimal manipulation of critically ill infants.

In adult-onset NPH, some clinicians believe that the best results from CSF shunting are achieved in patients who have the full clinical triad or who show improvement when 30 to 50 mL of CSF is removed by lumbar puncture. However, because brain NPH represents a potentially reversible form of dementia, other diagnostic techniques are used to improve the selection of patients likely to benefit from CSF shunting. The following tests are preferred by one or more groups, but none is universally accepted as reliably prognostic of a favorable outcome: CT or MRI evidence of transependymal diffusion of fluid; "isotope cisternography," a measure of the direction of CSF flow, showing CSF reflux from the subarachnoid space to the lateral ventricles (reversing the normal flow) and delayed clearance or intraventricular transependymal penetration of the isotope; CSF compartment infusion or perfusion tests; intracranial pressure monitoring to assess high-pressure waves; measurement of CSF blood flow; and dynamic MRI studies to determine the direction and volume of CSF flow. Cerebral angiography is occasionally indicated in diagnostic problems of hydrocephalus owing to intracranial mass lesions.

Prognosis and Treatment

Prognosis is sometimes related to an underlying disease (e.g., cerebral neoplasm), and treatment of hydrocephalus is palliative if it is given. However, present-day management of conditions such as brain tumor and cerebrovascular disease can yield prolongation of quality of life. Therefore, relief of obstructive hydrocephalus by a shunting procedure is often indicated to prevent acute brain herniation and death. In other cases, there may be spontaneous arrest, as in benign communicating hydrocephalus of infants. A shunting procedure may allow the underlying condition to stabilize or arrest. The patient's prognosis is then related to the severity of that condition (e.g., Dandy-Walker syndrome or status after basal arachnoiditis). In some patients (e.g., adult aqueductal stenosis), shunting can produce an excellent outcome. In untreated progressive infantile hydrocephalus, the mortality rate is 50% at age 1 year and 75% at age 10 years. After intracranial hemorrhage in high-risk premature infants, the outcome in hydrocephalus is usually related to factors (e.g., asphyxia) other than shunt responsiveness.

The problem of selecting patients with idiopathic NPH (as opposed to those who have had prior subarachnoid hemorrhage or meningitis) for CSF shunting persists. In the series of Vanneste and colleagues (1992,1993), 36% of patients with idiopathic NPH improved ([Table 48.1](#)), and 28% suffered complications of the procedure, with death or persistent disability in 7%. Complications included cerebral infarction and hemorrhage, subdural hematoma or effusion, intracranial infection, seizures, and extracranial infections. Of 166 patients, 32 had shunt revisions.

Cause of NP	Patients (n)	Grade of Improvement		
		None	Slight	Marked
Idiopathic	127	87	21	19 (15%)
Known cause				
Communicating	11	7	0	4 (36%)
Noncommunicating	14	3	2	9 (64%)
Total	152	97	23	32
Percent		64%	15%	21%

Modified from Vanneste et al., 1992.

TABLE 48.1. RESULTS OF CEREBROSPINAL FLUID SHUNTING FOR NORMAL PRESSURE HYDROCEPHALUS (NPH)

Higher rates of improvement have been reported; however, favorable results are more likely to be reported. The best results are attained in patients who have no adverse risk factors, clear evidence of dementia and ataxia with or without urinary incontinence, CT evidence of chronic hydrocephalus, and normal CSF at lumbar puncture.

Pharmacologic therapy is of limited value; there have been favorable reports of acetazolamide (Diamox), furosemide (Lasix), and isosorbide use, with or without repeated lumbar punctures. The major therapeutic choice is surgery, including choroid plexectomy for papilloma. Numerous CSF shunting procedures have been advocated to effect CSF removal from one portion of the craniospinal space to another (ventriculocisternal shunting) or from the craniospinal space to an extracranial reservoir (ventriculopleural shunt). Results vary with the procedures used, operative techniques, patient status, cause and duration of hydrocephalus, and incidence of complications, such as infection, subdural hematoma, shunt failure, or seizures.

Ventricular enlargement begins immediately and is grossly evident within 3 hours of experimental obstruction of the fourth ventricle in monkeys. After 3 weeks, damage is irreversible. If these experimental results apply to humans, early intervention is indicated. Even when management of progressive infantile hydrocephalus is optimal, the survival rate is 50% after age 15 years, with 15% incidence of mental retardation. In NPH, the success rate is best in patients with recent progression of mild dementia, gait disorder, and urinary incontinence. Under those circumstances, 60% of patients may show improvement, but a complication rate of 35% is not uncommon.

CHAPTER 49. BRAIN EDEMA AND DISORDERS OF INTRACRANIAL PRESSURE

ROBERT A. FISHMAN

[Brain Edema](#)
[Idiopathic Intracranial Hypertension](#)
[Spontaneous Intracranial Hypotension](#)
[Suggested Readings](#)

BRAIN EDEMA

Brain edema accompanies a wide variety of pathologic processes. It plays a major role in head injury, stroke, and brain tumor, as well as in cerebral infections, including brain abscess, encephalitis, and meningitis; lead encephalopathy; hypoxia; hyposmolality; the dysequilibrium syndromes associated with dialysis and diabetic ketoacidosis; Reye syndrome; fulminant hepatic encephalopathy; and hydrocephalus. Brain edema occurs in several different forms; clearly it is not a single pathologic or clinical entity.

Brain edema is defined as an increase in brain volume due to an increase in water and sodium content. Brain edema, when well localized or mild in degree, is associated with little or no clinical evidence of brain dysfunction; however, when it is severe, it causes focal or generalized signs of brain dysfunction, including various forms of brain herniation and medullary failure of respiration and circulation. The major forms of herniation are uncal, cerebellar tonsillar, upward cerebellar, cingulate, and transcalvarial herniation.

Brain edema and brain engorgement are different processes. *Brain engorgement* is an increase in the blood volume of the brain caused by obstruction of the cerebral veins and venous sinuses or by arterial vasodilatation, such as that caused by hypercapnia. Focal or generalized brain edema results in intracranial hypertension when it is severe enough to exceed the compensatory mechanisms modulating intracranial pressure.

Brain edema is classified into three major categories: vasogenic, cellular (cytotoxic), and interstitial (hydrocephalic). The features of the three forms of cerebral edema are summarized in [Table 49.1](#) in terms of pathogenesis, location and composition of the edema fluid, and changes in capillary permeability.

	Vasogenic	Cellular	Interstitial (Hydrocephalic)
Pathogenesis	Increased capillary permeability	Cellular swelling (glia, neurons, endothelial)	Increased brain fluid due to block of CSF absorption
Location of edema	Diffuse, white matter	Grey and white matter	Diffuse, periventricular white matter
Edema fluid composition	Plasma (protein including plasma protein)	Increased intracellular water and sodium	CSF
Extracellular fluid volume	Increased	Decreased	Increased
Capillary permeability to large molecules (immunoglobulin, serum albumin, iodine)	Increased	Normal	Normal
Clinical disorders	Brain tumor, abscess, infarction, trauma, hemorrhage, lead encephalopathy, hypoxic-ischemic, hypoxic-ischemic (postanoxic) edema	Hyponatremia, hypoxia, water intoxication, hypoxic-ischemic, ischemic, hypoxic-ischemic (postanoxic) edema, fulminant hepatic encephalopathy	Obstructive hydrocephalus, idiopathic (benign) intracranial hypertension, or normal-pressure hydrocephalus (chronic)
EEG changes	Focal slowing common	Generalized slowing	Often normal
Therapeutic effects	Beneficial in brain tumor, abscess	No effect (if fulminant hepatic encephalopathy)	Uncertain effectiveness
Concomitants	Reduces volume of normal brain (see only edema)	Reduces brain volume acutely	None useful

TABLE 49.1. CLASSIFICATION OF BRAIN EDEMA

Vasogenic Edema

Vasogenic edema is characterized by increased permeability of brain capillary endothelial cells to macromolecules, such as the plasma proteins whose entry is limited by the capillary endothelial cells. The increase in permeability is visualized when contrast enhancement is observed with computed tomography (CT). Increased cerebrospinal fluid (CSF) protein levels are also indicative of increased endothelial permeability. Magnetic resonance imaging (MRI) is more sensitive than CT in demonstrating the increases in brain water and extracellular volume that characterize vasogenic edema.

Vasogenic edema is characteristic of clinical disorders in which contrast-enhanced CT is frequently positive or MRI shows increased signal intensity. These disorders include brain tumor, abscess, hemorrhage, infarction, and contusion. These radiologic changes are also seen with acute demyelinating lesions in multiple sclerosis. They also occur with lead encephalopathy or purulent meningitis. The functional manifestations of vasogenic edema include focal neurologic deficits, focal electroencephalogram (EEG) slowing, disturbances of consciousness, and severe intracranial hypertension. In patients with brain tumor, whether primary or metastatic, the clinical signs are often caused more by the surrounding edema than by the tumor mass itself.

Cellular (Cytotoxic) Edema

Cellular edema is characterized by swelling of all the cellular elements of the brain (neurons, glia, and endothelial cells), with a concomitant reduction in the volume of the extracellular fluid space of the brain. Capillary permeability is not usually affected in the various cellular edemas; patients so affected have a normal CSF protein and isotopic brain scan. CT does not reveal contrast enhancement, and MRI is usually normal.

There are several causes of cellular edema: hypoxia, acute hyposmolality of the plasma, and osmotic dysequilibrium syndromes. *Hypoxia* after cardiac arrest or asphyxia results in cerebral energy depletion. The cellular swelling is determined by the appearance of increased intracellular osmoles (especially sodium, lactate, and hydrogen ions) that induce the rapid entry of water into cells. *Acute hyposmolality of the plasma* and extracellular fluid is caused by acute dilutional hyponatremia, inappropriate secretion of antidiuretic hormone, or acute sodium depletion. *Osmotic dysequilibrium syndromes* occur with hemodialysis or diabetic ketoacidosis, in which excessive brain intracellular solutes result in excessive cellular hydration when the plasma osmolality is rapidly reduced with therapy. In uremia, the intracellular solutes presumably include a number of organic acids recovered in the dialysis bath. In diabetic ketoacidosis, the intracellular solutes include glucose and ketone bodies; however, there are also unidentified, osmotically active, intracellular solutes, termed *idiogenic osmoles*, that favor cellular swelling.

Major changes in cerebral function occur with the cellular edemas, including stupor, coma, EEG changes and asterixis, myoclonus, and focal or generalized seizures. The encephalopathy is often severe with acute hyposmolality, but in more chronic states of hyposmolality of the same severity, neurologic function may be spared. Acute hypoxia causes cellular edema, which is followed by vasogenic edema as infarction develops. Vasogenic edema increases progressively for several days after an acute arterial occlusion. The delay in obtaining contrast enhancement with CT following an ischemic stroke illustrates that time is needed for defects in endothelial cell function to develop.

Ischemic Brain Edema

Most patients with arterial occlusion have a combination of cellular edema first and then vasogenic edema, together termed *ischemic brain edema*. The cellular phase takes place after acute ischemia over minutes to hours and may be reversible. The vasogenic phase takes place over hours to days and results in infarction, a largely irreversible process, although the increased endothelial cell permeability usually reverts to normal within weeks.

Fulminant Hepatic Encephalopathy

Acute hepatocellular failure occurs secondary to acute viral or toxic hepatitis and in Reye syndrome, a disorder affecting children. The resulting encephalopathy is characterized by progressive stupor and coma. Severe intracranial hypertension with brain edema is a major and often fatal complication. Imaging studies reveal a

“tight” brain with normal permeability to contrast material.

Interstitial (Hydrocephalic) Edema

Interstitial edema is the third type of edema, best characterized in obstructive hydrocephalus, in which the water and sodium content of the periventricular white matter is increased because of the movement of CSF across the ventricular walls. Obstruction of the circulation of the CSF results in the transependymal movement of CSF and thereby an absolute increase in the volume of the extracellular fluid of the brain. This is observed in obstructive hydrocephalus with CT and MRI. Low-density changes are observed at the angles of the lateral ventricles. The chemical changes are those of edema, with one exception: The volume of periventricular white matter is reduced rather than increased. After successful shunting of CSF, interstitial edema is reduced, and the thickness of the mantle is restored.

Functional manifestations of interstitial edema are usually relatively minor in chronic hydrocephalus, unless the changes are advanced, when dementia and gait disorder become prominent. The EEG is often normal in interstitial edema. This finding indicates that the accumulation of CSF in the periventricular extracellular fluid space is much better tolerated than is the presence of plasma in the extracellular fluid space, as seen with vasogenic edema, which is characterized by focal neurologic signs and EEG slowing.

Granulocytic Brain Edema

Severe brain edema occurs with brain abscess and purulent meningitis due to collections of pus, which are often sterile as a result of antibiotic treatment. Such edema, associated with membranous products of granulocytes (pus), has been termed *granulocytic brain edema*. The features of cellular and vasogenic edema occur concurrently in purulent meningitis, and in severe cases hydrocephalic edema also develops, so that granulocytic brain edema may include the features of all three types of brain edema.

Therapeutic Considerations

The therapy of brain edema depends on the cause. Appropriate and early treatment of intracranial infection is essential. Surgical therapy is directed toward alleviating the cause by excision or decompression of intracranial mass lesions as well as by a variety of shunting procedures. A patent airway, maintenance of an adequate blood pressure, and the avoidance of hypoxia are fundamental requirements in the care of these patients.

The administration of appropriate parenteral fluids to meet the needs of patients is also essential. Administration of salt-free fluids should be avoided. In patients with cerebral edema, serum hypoosmolality has deleterious effects and should be avoided.

The pharmacologic treatment of brain edema is based on the use of glucocorticoids, osmotherapy, and drugs that reduce CSF formation. Hyperventilation, hypothermia, and barbiturate therapy have also been tested experimentally and in clinical practice; they are hardly ever used.

Glucocorticoids

The rationale for the use of steroids is largely empiric. Glucocorticoids dramatically and rapidly (in hours) begin to reduce the focal and general signs of brain edema around tumors. The major mechanism explaining their usefulness in vasogenic brain edema is a direct normalizing effect on endothelial cell function and permeability.

The biochemical basis of the changes in membrane integrity that underlie vasogenic and cellular edema is now under study. Attention has focused on the role of free radicals (i.e., superoxide ions, hydroxyl radicals, singlet oxygen, and nitric oxide) and on the effects of polyunsaturated fatty acids, most notably arachidonic acid, in the peroxidation of membrane phospholipids. The ability of adrenal glucocorticoids to inhibit the release of arachidonic acid from cell membranes may explain their beneficial effects in vasogenic edema; however, steroids have not been shown to be therapeutically useful in the brain edema of hypoxia or ischemia. Cellular damage is more important than brain edema in these conditions.

Long-acting, high-potency glucocorticoids are the most widely used. The usual dosage of dexamethasone is a starting dose of 10 mg followed by 4 mg administered four times a day thereafter—a dose equivalent in potency to 400 mg of cortisol daily. These large doses are about 20 times the normal rate of human endogenous cortisol production. Even larger dosages are sometimes used. Insufficient data are available to establish a formal dose–response curve for steroids in the treatment of brain edema; dosage schedules remain empiric.

Although any of the usual complications of steroid therapy are to be expected, gastric hemorrhage is usually the most troublesome. Fortunately, convulsive seizures apparently have not been increased in frequency by high dosages of the glucocorticoids. The risks of increased wound infection and impaired wound healing appear to be outweighed by the therapeutic effects in most patients receiving short-term therapy.

Although published data indicate that dexamethasone is valuable in the treatment of vasogenic edema associated with brain tumor and abscess, the literature recommending its use in stroke has, in general, been poorly documented and is controversial. Steroids may be useful in the treatment of intracerebral hematoma with extensive vasogenic edema due to the mass effect of the clot. In head injury, steroid therapy has frequently been used. Although some effectiveness following trauma has been documented, reductions in morbidity and mortality attributable to steroids are not great. The role of megadose steroids in the treatment of acute spinal cord injury is discussed elsewhere.

There are no convincing data, clinical or experimental, that glucocorticoids have beneficial effects in the cellular edema associated with hypoosmolality, asphyxia, or hypoxia in the absence of infarction with mass effects. There is little basis for recommending steroids in the treatment of the cerebral edema associated with cardiac arrest or asphyxia. The use of steroids in the management of fulminant hepatic encephalopathy is controversial. There are no controlled data regarding its effectiveness.

When intracranial hypertension and obstructive hydrocephalus occur because of inflammatory changes in the subarachnoid space or at the arachnoid villi, whether attributable to leukocytes or to blood, there is a reasonable rationale for the use of steroids. Despite the frequent use of steroids in purulent or tuberculous meningitis, however, few data are available to document the effectiveness of steroids against the acute disease. There are conflicting reports about the efficacy of steroids in acute bacterial meningitis or tuberculous meningitis. Use of steroids has not been shown to affect the subsequent incidence of chronic sequelae, such as obstructive hydrocephalus or seizures. Steroids do reduce the incidence of deafness in infants with bacterial meningitis. Steroids appear useful in the management of other conditions characterized by an inflammatory CSF, such as chemical meningitis following intrathecal radioiodinated serum albumin, meningeal sarcoidosis, or cysticercosis.

Osmotherapy

Hypertonic mannitol (Osmitol) is the most widely used solute for the treatment of intracranial hypertension associated with brain edema. The effectiveness of osmotherapy depends on several factors. First, it is effective in reducing brain volume and elastance only as long as an osmotic gradient exists between blood and brain. Second, osmotic gradients obtained with hypertonic parenteral fluids are short-lived because the solute reaches an equilibrium concentration in the brain after a delay of only a few hours. Third, the parts of the brain most likely to “shrink” are normal areas; thus, with focal vasogenic edema, the normal regions of the hemisphere shrink, but edematous regions with increased capillary permeability do not. Fourth, a rebound in the severity of the edema may follow use of any hypertonic solution because the solute is not excluded from the edematous tissue; if tissue osmolality rises, the tissue water is increased. Finally, there is scant rationale for long-term use of hypertonic fluids, either orally or parenterally, because the brain adapts to sustained hyperosmolality with an increase in intracellular osmolality due to the solute and to idiogenic osmoles.

There is some uncertainty about the size of an increase in plasma osmolality that causes a therapeutically significant decrease in brain volume and intracranial pressure in humans. Acute increases as small as 10 mOsm/L may be therapeutically effective. It should be emphasized that accurate dose–response relationships in different clinical situations have not been well- defined with mannitol.

Other Therapeutic Measures

Hyperventilation, hypothermia, and barbiturates have been used in the management of intracranial hypertension, but none is established, and the extensive literature is not reviewed here. Acetazolamide (Diamox) and furosemide (Lasix) reduce CSF formation in animals and have limited usefulness in the management of interstitial edema.

IDIOPATHIC INTRACRANIAL HYPERTENSION

Idiopathic intracranial hypertension (IIH) describes a heterogeneous group of disorders characterized by increased intracranial pressure when intracranial mass lesions, obstructive hydrocephalus, intracranial infection, and hypertensive encephalopathy have been excluded. IIH is also termed *pseudotumor cerebri*. In the past, it has also been referred to as "serous meningitis" and "otitic hydrocephalus." The term *benign* has also been used because spontaneous recovery is characteristic, but serious threats to vision make accurate diagnosis and therapeutic intervention a necessity.

Various pathologic conditions are associated with IIH, although in most cases the pathogenesis of the intracranial hypertension is poorly understood:

Endocrine and metabolic disorders

- Obesity and menstrual irregularities
- Pregnancy and postpartum (without sinus thrombosis)
- Menarche
- Female sex hormones
- Addison disease
- Adrenal steroid withdrawal
- Hyperadrenalism
- Acromegaly
- Hypoparathyroidism

Intracranial venous-sinus thrombosis

- Mastoiditis and lateral sinus thrombosis
- After head trauma
- Pregnancy and postpartum
- Oral progestational drugs
- "Marantic" sinus thrombosis
- Cryofibrinogenemia
- Primary (idiopathic) sinus thrombosis

Drugs and toxins

- Vitamin A
- Retinoic acid
- Tetracycline
- Nalidixic acid (NegGram)
- Chlordecone (Kepone)
- Danazol (Danocrine)
- Amiodarone hydrochloride (Cordarone)
- Lithium carbonate
- Nitrofurantoin

Hematologic and connective tissue disorders

- Iron deficiency anemia
- Infectious mononucleosis
- Lupus erythematosus

High CSF protein content

- Spinal cord tumors
- Polyneuritis

"Meningism" with systemic bacterial or viral infections

Empty-sella syndrome

Miscellaneous

- Sydenham chorea
- Familial syndromes
- Rapid growth in infancy

Idiopathic conditions

Symptomatic intracranial hypertension without localizing signs may simulate IIH. Such conditions include obstructive hydrocephalus, chronic meningitis (sarcoïd, fungal, or neoplastic), hypertensive encephalopathy, pulmonary encephalopathy due to paralytic hypoventilation, obstructive pulmonary disease, or the pickwickian syndrome (morbid obesity). High-altitude cerebral edema is an unusual manifestation of hypoxia.

Clinical Manifestations

The presenting symptoms are headache and impaired vision. The headache may be worse on awakening and aggravated by coughing and straining. It is often mild or may be entirely absent. The most common ocular complaint is visual blurring, a manifestation of papilledema. Some patients complain of brief, fleeting movements of dimming or complete loss of vision, occurring many times during the day (amaurosis fugax), at times accentuated or precipitated by coughing and straining. This ominous symptom indicates that vision is in jeopardy. Visual loss may be minimal despite severe chronic papilledema, including retinal hemorrhages; however, blindness occasionally develops rapidly (i.e., less than 24 hours). Visual fields characteristically show enlargement of the blind spots and may show constriction of the peripheral fields and central or paracentral scotoma. Diplopia caused by unilateral or bilateral sixth nerve palsy may develop as a result of increased intracranial pressure. The neurologic examination is otherwise normal. A major clinical point is that patients with IIH usually look well; their apparent well-being belies the ominous appearance of the papilledema. Although the disorder most often lasts for months, it may persist for years without serious sequelae. Remissions may be followed by one or more recurrences in 5% to 10% of cases. In some patients, IIH may be responsible for development of the *empty-sella syndrome*, in which radiographic enlargement of the sella turcica simulates a pituitary tumor. CT reveals that the enlarged sella is filled with CSF due to a defect of its diaphragm.

Pathophysiology

Several mechanisms have been considered as possible explanations for the pathophysiology of IIH. These include an increased rate of CSF formation, a sustained increase in intracranial venous pressure, a decreased rate of CSF absorption by arachnoid villi apart from venous occlusive disease, and an increase in brain volume due to an increase in blood volume or extravascular fluid volume, simulating a form of brain edema.

No data are available regarding the rate of CSF formation in IIH because the only reliable method for measurement (ventriculocisternal perfusion) is not applicable to these patients. The only condition in which increased CSF formation has been demonstrated is choroid plexus papilloma. Increased CSF production might explain the pathophysiology in some of the diverse conditions associated with IIH, but this mechanism remains unproven. A sustained increase in intracranial venous pressure associated with decreased CSF absorption readily explains the pathophysiology of IIH associated with venous-sinus thrombosis. Increased venous-sinus pressures are readily transmitted to the CSF and would also interfere with CSF absorption. Decreased CSF absorption (in the absence of venous occlusion) due to altered function of the arachnoid villi would explain the occurrence of IIH in some cases; this reasonable hypothesis is also unproven. The fact that IIH is associated with normal or small ventricles rather than hydrocephalus is consonant with such a mechanism. Abnormal spinal infusion tests do not differentiate between impairment of CSF absorption and decreased intracranial compliance. The occurrence of IIH in patients with polyneuritis or spinal cord tumors appears to support the hypothesis that defective CSF absorption may be the basis for the syndrome. This is not directly correlated with the degree of CSF protein elevation; it is presumed to depend on an alteration of the function of the arachnoid villi.

The hypothesis that IIH might be due to an increase in brain volume (a special form of brain edema) secondary to an increase in blood or extracellular fluid volume is supported by the presence of small ventricles, although this is an uncommon finding. An increase in brain volume would be expected if the extracellular space of the

brain were expanded; this might occur if there were an excessive amount of CSF in the brain owing to either increased formation or decreased absorption.

Any theory of the pathogenesis of IIH must be consonant with the rapid therapeutic response of IIH to shunting of CSF by a lumbar peritoneal shunt. Impaired CSF absorption or increased CSF formation would explain the occurrence of IIH in most cases; however, the limited data available do not allow any firm conclusions.

Endocrine and Metabolic Disorders

IIH is most commonly seen in healthy women with a history of menstrual dysfunction. Frequently, the women are moderately or markedly overweight (without evidence of alveolar hypoventilation). Menstrual irregularity or amenorrhea is common. Galactorrhea is an unusual associated symptom. The histories often emphasize excessive premenstrual weight gain. Endocrine studies have not revealed specific abnormalities of urinary gonadotropins or estrogens, and the pathogenesis is unknown. IIH has a complex relationship to adrenal hormones. Rarely is IIH a complication of Addison disease or Cushing disease. Improvement occurs after restoration of a normal adrenal state; the mechanism in either circumstance is unknown.

IIH has also occurred in patients treated with adrenal corticosteroids for prolonged periods. Many of the patients had allergic skin disorders or asthma during childhood; IIH generally occurred when the steroid dosage was reduced, but evidence of hyperadrenalism persisted. Hypoparathyroidism may also present with increased intracranial pressure; hypocalcemic seizures or cerebral calcifications may further complicate the clinical picture. IIH has been reported in women taking oral progestational drugs when angiography has excluded sinus thrombosis.

Intracranial Venous-sinus Thrombosis

Intracranial hypertension occurs secondary to occlusion of the intracranial venous sinuses as a consequence of acute or chronic otitis media with extension of the infection into the petrous bone and lateral sinus. The sixth cranial nerve may also be involved, giving rise to diplopia on lateral gaze. Thrombosis of the superior longitudinal sinus may occur after mild closed head injury, giving rise to IIH. Occlusion of this sinus, which drains both cerebral hemispheres, is more likely to result in hemorrhagic infarction of the cerebrum as the thrombosis extends into the cerebral veins, giving rise to bilateral signs. In such cases, the course is frequently fulminant and the prognosis guarded, although complete recovery may occur. Aseptic or primary thrombosis of the superior longitudinal sinus may also be responsible for a pseudotumor syndrome, especially as a complication of pregnancy; it has been reported in the first 2 to 3 weeks postpartum, as well as at the end of the first trimester of pregnancy. Sinus thrombosis has been reported with the use of oral progestational drugs. A coagulopathy is suggested as the basis for these events, although rarely has this been substantiated. Sinus thrombosis occurs as a complication of dehydration and cachexia ("marantic" thrombosis), particularly in infancy.

Drugs and Toxins

IIH has been reported in otherwise healthy adolescents taking huge doses of vitamin A for the treatment of acne. Oral doses as low as 25,000 U daily may cause headache and papilledema, with rapid improvement after cessation of the therapy. The syndrome is said to have occurred in Arctic explorers who consumed polar bear liver, a great source of vitamin A. Some cases of IIH, manifested by bulging fontanel and papilledema, have been reported in children given tetracycline or nalidixic acid. The mechanisms involved are obscure. Spontaneous, rapid recovery occurs when the drugs are stopped. The insecticide chlordecone, as well as amiodarone and lithium carbonate, has also been reported to cause IIH.

Hematologic and Connective Tissue Disorders

Papilledema and increased intracranial pressure have been attributed to severe iron deficiency anemia, with striking improvement after treatment of the anemia. Presumably, the mechanism partly reflects the marked increase in cerebral blood flow that accompanies profound anemia. IIH has been reported with infectious mononucleosis, but the mechanism is not known. It has also been observed as manifestation of systemic lupus erythematosus.

Pulmonary Encephalopathy

IIH can be a major complication of chronic hypoxic hypercapnia caused by paralytic states, such as muscular dystrophy and cervical myelopathy; it may also be a major complication of obstructive pulmonary disease and the pickwickian syndrome. There is a chronic increase of cerebral blood flow because of the anoxemia and carbon dioxide retention. Patients usually appear mentally dull and encephalopathic, and thus differ from most patients with IIH.

Spinal Cord Diseases

IIH rarely occurs with tumors of the spinal cord or cauda equina, or with polyneuritis. Papilledema and headache disappear with treatment of the spinal lesion or regression of the polyneuropathy. The mechanism may involve the effects of an elevated CSF protein on CSF absorption at the arachnoid villi in both cranial and spinal subarachnoid spaces. Occurrence of this syndrome, however, does not correlate with the degree of protein elevation.

Meningism is an old term that is applied to patients with stiff neck, increased intracranial pressure (usually 200 to 300 mm Hg), but an otherwise normal CSF. This syndrome occurs in patients with acute systemic viral infections such as influenza. The mechanism of the intracranial hypertension is unknown.

One of the more common forms of IIH appears in otherwise healthy persons in the absence of any of the aforementioned etiologic factors. Both sexes are affected, and the occurrence is most often between ages 10 and 50 years.

Diagnosis

The patient with headache and papilledema without other neurologic signs must be considered to have symptomatic intracranial hypertension due to intracranial infection until proven otherwise. This is true in about 35% of cases. Although the diagnosis of IIH may be suspected by the appearance of well-being and a history of some of the associated etiologic features listed previously, the diagnosis is essentially one of exclusion and depends on ruling out the more common causes of increased intracranial pressure. Brain tumor, particularly when located in relatively silent areas such as the frontal lobes or right temporal lobe, or when obstructing the ventricular system, may be manifested only by headache and papilledema. Patients with chronic subdural hematoma, without a history of significant trauma, may have the same symptoms.

Diagnostic evaluation depends on CT or MRI, which have obviated conventional angiography in most cases. MR venography promises to be the procedure of choice to exclude venous occlusion. Lumbar puncture should be deferred until CT indicates that the ventricular system is normal in size and location. Diagnostic lumbar puncture is mandatory to establish the diagnosis of IIH. In obesity, the normal upper limit of CSF pressure is 250 mm Hg. In IIH, the CSF pressure is elevated, usually between 250 and 600 mm Hg, but the fluid is otherwise normal. The protein content is often in the lower range of normal, and lumbar CSF protein levels of 10 to 20 mg/dL are common. A CSF protein content greater than 50 mg/dL, decreased CSF glucose, or increased cell count throws doubt on the diagnosis of IIH and suggests another disease.

Pseudopapilledema may be a source of diagnostic confusion. In this developmental anomaly of the fundus, the ophthalmologic appearance may be indistinguishable from true papilledema; there is elevation of the optic disc, although exudates and hemorrhages are absent. Visual acuity is normal, but visual fields may show enlargement of the blind spots. The unchanging appearance of the fundus in subsequent examinations favors the diagnosis of pseudopapilledema, as does the finding of normal CSF pressure on lumbar puncture. Optic neuritis is differentiated from IIH by visual loss and normal CSF pressure.

Treatment

The common form of IIH in patients with menstrual disorders and obesity requires individualized management. This syndrome is self-limited in most cases, and after some weeks or months, spontaneous remissions occur, making evaluation of therapy difficult. Recurrent episodes have been noted in about 5% to 10% of patients, and the illness seldom lasts for years. In the extremely obese, weight reduction is recommended. Daily lumbar puncture was used in the past to lower CSF pressure to normal levels by removing sufficient fluid; 15 to 30 mL of fluid may be removed, but the value of this procedure is dubious. A CSF shunting procedure, such as a lumboperitoneal shunt, is useful in patients with intractable headache and progressive visual impairment. It may dramatically relieve symptoms. Optic nerve

decompression has its advocates as the procedure of choice to preserve vision.

Dexamethasone has been used empirically because it minimizes cerebral edema of diverse causes and seems effective in some patients. Steroids, however, should be avoided unless acetazolamide and furosemide fail because hyperadrenocorticism may precipitate IIH. Acetazolamide has been used because this carbonic anhydrase inhibitor reduces CSF formation. Furosemide also reduces CSF formation in animals and is useful. Hypertonic intravenous solutions (25% mannitol) to lower intracranial pressure can be used in acute situations when there is rapidly failing vision and surgical intervention is awaited; however, prolonged dehydration therapy is deleterious. Use of oral glycerol has the disadvantage of high caloric intake for obese patients. Subtemporal decompression was widely used in the past, but its efficacy has been questioned. Either lumboperitoneal shunts or optic nerve decompression is used to treat progressive visual loss. Their comparative risks and benefits should be assessed on an individual basis.

In patients with lateral sinus thrombosis caused by chronic infection in the petrous bone, surgical decompression may be indicated. When the pseudotumor syndrome is a manifestation of hypoadrenalism or hypoparathyroidism, replacement therapy is indicated. Vitamin A intoxication disappears when administration of the vitamin is stopped. Anticoagulation therapy is recommended for some patients with dural-sinus thrombosis; however, with extension of the clot into cerebral veins and hemorrhagic infarction of tissue, anticoagulation is useful despite its hazards. Thrombolytic therapy has been used successfully in recent reports.

SPONTANEOUS INTRACRANIAL HYPOTENSION

In 1938, Schaltenbrand described the occurrence of primary spontaneous intracranial hypotension (SIH), or “essential aliquorrhoea.” The symptoms were self-limited, resolving spontaneously within several weeks to several months. Decreased choroidal secretion and increased CSF reabsorption were suggested as possible mechanisms, but evidence for either was lacking.

Spontaneous cryptic CSF leaks via dural fistulas adjacent to the spinal roots have been identified with radionuclide cisternography and contrast myelography. The defects appear to reflect rupture of arachnoid (Tarlov) cysts that occurred without trauma. The rapid urinary excretion of radioisotope following intraspinal injection of the tracer reflects such spinal dural deficits. This diagnosis has been established with an intraspinal combined injection of technetium-albumin and myelographic contrast material. In some cases, one agent alone may identify the leak, which explains the advantage of the double injection. Cervical injection (C-2 or C-3) is often preferred over lumbar injection because it is less likely to result in a postlumbar-puncture headache and the cervical region is distant from the more common sites of leakage in the thoracolumbar region.

Gadolinium-enhanced MRI has revealed striking diffuse dural enhancement with CSF hypotension due to a CSF fistula associated with a “sagging” brain (i.e., flattening of the optic chiasm, displacement of the pons against the clivus, and the cerebellar tonsils below the level of the prepontine cistern simulating a Chiari malformation). Venous engorgement of the venous sinus is also observed. These changes rapidly resolve after closure of the CSF fistula. [Figure 49.1](#) shows the characteristic MR findings in the sagging brain, together with their resolution 5 days after a successful epidural lumbar blood patch. The dural enhancement reflects the Monro-Kellie rule: Intracranial venous engorgement results from a reduced CSF volume.

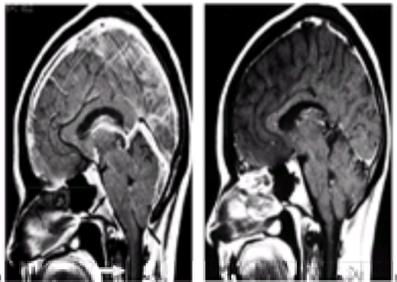

FIG. 49.1. Sagging brain in spontaneous intracranial hypotension. **A:** Gadolinium-enhanced T1-weighted sagittal MR image prior to lumbar epidural blood patch demonstrates enhancement of the dura, venous engorgement, displacement of the pons and cerebellum below the level of the prepontine cistern (*arrow*), and inferior displacement of the optic chiasm and third ventricle (*arrow*). **B:** Gadolinium-enhanced T1-weighted images 5 days after large-volume (20 mL) lumbar epidural blood patch show resolution of dural enhancement and restoration of the cisterns, with elevation of the pons, tonsils, and optic chiasm. (From Fishman and Dillon, 1993; with permission.)

SIH usually resolves spontaneously or with bedrest, analogous to postlumbar-puncture headache. For intractable cases, treatment with a large-volume lumbar epidural blood patch is usually preferred, with the head and spine then tilted downward (30 degrees) for 10 minutes to facilitate the movement of blood extradurally to the thoracic and cervical regions. In persistent cases, surgical closure of the fistula may be necessary.

Although postural headaches in the erect position are typical of SIH, some patients are headache-free despite characteristic radiologic changes. The occurrence of somnolence and stupor due to a sagging brain has been observed. SIH may simulate an acquired Chiari I malformation. Multiple cranial nerve signs have been noted, including binasal field defects, diplopia, tinnitus, and hearing loss.

CHAPTER 50. SUPERFICIAL SIDEROSIS OF THE CENTRAL NERVOUS SYSTEM

ROBERT A. FISHMAN

[Suggested Readings](#)

Superficial siderosis is the deposition of hemosiderin over the pial surfaces and superficial neuropil of the brain and spinal cord. It is usually characterized by sequential development of sensorineural deafness and cerebellar ataxia followed by myelopathy, anosmia, and dementia. The condition usually evolves for many years as a consequence of chronic, intermittent, or persistent oozing of blood into the cerebrospinal fluid (CSF). The bleeding may be cryptic, that is, asymptomatic and unassociated with headache, backache, or signs of meningeal irritation. A common error is the faulty clinical diagnosis of a neurodegenerative disorder, cerebellar degeneration with deafness.

In the past, the condition was recognized chiefly at autopsy by the rust-colored appearance of the affected structures. Computed tomography (CT) and particularly magnetic resonance imaging (MRI) have shown that the condition is far more frequent than previously suspected. MRI has greater sensitivity because the strong paramagnetic effect of iron-containing compounds allows better visualization in T2-weighted images, which show striking rims of hypointensity over the surfaces of the cerebrum and particularly over the cerebellar vermis and adjacent cortical sulci. Hypointensities are observed rimming the brainstem and especially along the eighth cranial nerve, which is the most vulnerable cranial nerve because it is covered in the subarachnoid space by oligodendroglia, and not by the Schwann cells that cover the nerve roots and peripheral nerves. The first and second cranial nerves and spinal cord are similarly vulnerable. The Bergmann radial glia of the cerebellum are also susceptible to the deposition of iron pigments, perhaps because they can synthesize ferritin more readily than other neural cells. The presence of xanthochromic CSF, often without a cellular reaction, should alert the clinician that a patient with insidiously progressive ataxia and deafness may have superficial siderosis. T2-weighted MR imaging is more likely to establish the diagnosis than CT, which is less sensitive ([Fig. 50.1](#)).

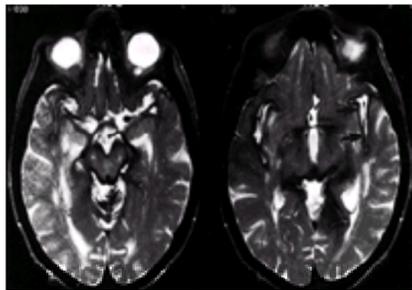

FIG. 50.1. Patient with 10-year history of progressive cerebellar ataxia, deafness, cognitive impairment, spasticity, and xanthochromic CSF. T2-weighted MR images show deposition of low-signal hemosiderin on the surfaces of the midbrain, cerebellar folia, and cerebral cortex adjacent to the sylvian cisterns (*arrows*). (Courtesy of Dr. William P. Dillon.)

The treatment of superficial siderosis requires identifying and treating the bleeding source, usually obvious in patients with aneurysms, vascular malformations, and tumors—especially ependymomas—of the brain or spinal cord. Siderosis may follow successful treatment of cerebellar tumors. Fearnley and colleagues (1995) reported identifying the precise source of bleeding in only about 50% of patients. Improvements in MRI should increase the success rate. There have been several reports of siderosis developing in patients with a variety of spinal dural defects, such as posttraumatic root avulsions, or with postoperative pseudomeningoceles following laminectomy. Closure of these dural defects arrests the progressive neurologic injury that results from chronic subarachnoid bleeding. Iron chelating agents have been ineffective in experimental animal models.

CHAPTER 51. HYPEROSMOLAR HYPERGLYCEMIC NONKETOTIC SYNDROME

LEON D. PROCKOP AND STEPHAN A. MAYER

[Suggested Readings](#)

The hyperosmolar hyperglycemic nonketotic syndrome (HHNS) is characterized by an abnormally high serum glucose level, high osmolality, and a depressed level of consciousness in the absence of ketoacidosis. Modern awareness of the syndrome is ascribed to Sament and Schwartz, who in 1957 described diabetic stupor without ketosis. By 1968, the neurologic symptoms and signs of seizures and metabolic encephalopathy were well recognized. HHNS occurs in 10% to 20% of all patients with severe hyperglycemia; it is most common in elderly patients with mild adult-onset diabetes mellitus. Death ensues in 40% to 50%, usually related to medical comorbidity or neurologic complications.

HHNS is defined by serum osmolality greater than 350 mOsm/kg, plasma glucose content greater than 600 mg/dL, and no ketosis in a patient with depressed consciousness. Often, the patient is lethargic or confused; coma is unusual. The degree of lethargy correlates with the level of hyperosmolality. Serum glucose levels are usually much higher than in diabetic ketoacidosis. Acidemia, Kussmaul respiration, and acetone on the breath are absent.

The average age of patients with HHNS is 60 years; men and women are affected equally. In most patients, the diabetes was not previously recognized, and only a few are insulin-dependent. Most patients with HHNS have some associated illness or medical therapy that precipitated the syndrome. Frequently associated illnesses include chronic renal insufficiency, gram-negative pneumonia or sepsis, gastrointestinal hemorrhage, myocardial infarction, pulmonary embolism, subdural hematoma, stroke, pancreatitis, and burns. Medications implicated in HHNS include diuretic agents (hydrochlorothiazide, furosemide [Lasix], ethacrynic acid [Edecrin]), corticosteroids, phenytoin sodium (Dilantin), propranolol, cimetidine, diazoxide, chlorpromazine hydrochloride (Thorazine), loxapine (Loxitane), asparaginase (Elspar), and immunosuppressive agents. Hyperalimentation, peritoneal dialysis or hemodialysis, and recent cardiac surgery have also been implicated.

Symptoms begin with several days or weeks of polyuria and polydipsia followed by dehydration and altered mental status. Depressed consciousness plays a key role in the development of the syndrome by preventing the patient from taking fluids in response to thirst. Confusion or unresponsiveness usually precipitates medical attention. Other neurologic findings include seizures (sometimes status epilepticus or epilepsia partialis continua), hemiparesis, aphasia, hemianopsia, visual loss, visual hallucinations, nystagmus, pupillary reflex abnormalities, asymmetric caloric responses, dysphagia, hyperreflexia, myoclonus, Babinski signs, and urinary retention. Systemic signs of dehydration include orthostatic hypotension, poor skin turgor, dry mucous membranes, and reduced sweating. The differential diagnosis includes diabetic ketoacidosis, alcoholic ketoacidosis, lactic acidosis, hepatic failure, uremia, hypoglycemia, drug ingestion, and stroke.

The diagnosis of HHNS is made in the laboratory. The serum glucose level ranges from 600 to 2,700 mg/dL, and serum osmolality is in the range of 325 to 425 mOsm/kg. A difference between the measured and calculated osmolality (calculated osmolality (mOsm/L) = $2 \times [\text{Na}^+] + [\text{glucose}]/18 + [\text{BUN}]/2.8$) indicates the presence of an unmeasured solute, such as mannitol or ethylene glycol. Although ketones are absent, mild acidosis with an elevated anion gap is present in 50% of patients (pH range, 6.8 to 7.4). In some patients, an element of lactic acidosis can result from hypotension and poor tissue perfusion, although this never completely accounts for the anion gap. Mixed acid-base disturbances may be present in patients with a metabolic alkylolysis due to diuretic use.

Plasma sodium concentrations vary over a wide range (120 to 180 mEq/L), although most patients are mildly hypernatremic. Elevated plasma glucose levels tend to depress the plasma sodium concentration (for every 100 mg/dL increment in glucose, sodium falls by 1.8 mEq/L). Therefore, a substantial free-water deficit may exist, even if the plasma sodium concentration is normal. Hypokalemia usually results from the sustained osmotic diuresis, and severe prerenal azotemia is the rule. In addition to laboratory studies, search for an underlying illness should include an electrocardiogram to rule out myocardial ischemia, blood and urine cultures and a chest x-ray to rule out infection, and brain computed tomography or magnetic resonance imaging if focal neurologic signs are present.

HHNS evolves when a physiologic stress and decreased insulin activity induce hyperglycemia. The hyperglycemia in turn induces an osmotic diuresis that continues until intravascular volume depletion reduces renal perfusion. The resulting free-water deficit and hyperosmolality cause cellular dehydration in both cerebral and extracerebral tissues, as water moves down the osmotic gradient from the intracellular to the extracellular compartment. Sodium and potassium losses occur as the osmotic diuresis interferes with normal tubular reabsorption, but water is always lost out of proportion to sodium, resulting in further extracellular hypertonicity. Cerebral dehydration is thought to be the primary cause of the neurologic changes of HHNS.

Treatment focuses on replacing volume deficits, correcting hyperosmolality, and managing any underlying illness. Patients in shock need immediate resuscitation with normal saline. The average total fluid deficit is 9 to 12 L. Central venous pressure monitoring may be useful in guiding therapy. Normal saline should be given until the blood pressure and urine output stabilize, at which point half-normal saline can be used. It is recommended that one-half of the estimated fluid deficit be replaced in the first 12 to 24 hours and the remainder replaced over the next few days.

Insulin may or may not be necessary in the initial management of HHNS. Serum glucose levels may drop by 25% with fluid replacement alone. Insulin is necessary if the patient is acidotic, hyperkalemic, or in renal failure. If insulin is used, a low-dose regimen should be given, that is, an initial intravenous bolus of 0.10 U/kg of regular insulin followed by a continuous intravenous infusion of 0.10 U/kg per hour. To avoid "overshoot" hypoglycemia, glucose levels should be monitored hourly; once they fall below 300 mg/dL, insulin is discontinued, and 5% dextrose is added to the infusion.

Most patients have total-body potassium deficits. Hydration and insulin administration further depress the serum potassium level. Therefore, potassium should be administered early in treatment.

If seizures develop, phenytoin should not be administered as initial therapy. It is ineffective in controlling seizures owing to hyperosmolality and inhibits the release of endogenous insulin. Seizures may be controlled with intravenous benzodiazepines until the metabolic disturbance is corrected.

Because of the high mortality rate of patients with HHNS and the meticulous monitoring that treatment requires, these patients are best managed in an intensive care unit.

EPIDEMIOLOGY

Nowhere else in oncology has there been a more vigorous explosion of research and therapy than in neurooncology. About 24,000 primary brain tumors are diagnosed each year in the United States alone. The estimated incidence for all ages, as determined from data largely collected before the era of computed tomography (CT), is 8.2 per 100,000 people ([Table 52.1](#)). Brain tumors are diagnosed more and more frequently, particularly in the growing number of elderly people. Brain tumors account for 20% of malignancies before age 15 years. There is a peak incidence in childhood, a steady rise from age 20 to age 70, and a decline thereafter ([Fig. 52.1](#)). Histologic type and location of tumors also vary by age and sex ([Table 52.2](#)). Rates in men are higher than in women for glioma, but the opposite occurs for meningioma. In children, medulloblastoma and astrocytomas predominate. In adults, gliomas and meningiomas are the most common, constituting, respectively, about 60% and 20% of all primary brain tumors in this age group. In children, 70% of tumors are located beneath the tentorium, compared to 30% in adults. Survival differs by age group; central nervous system (CNS) tumors in children tend to have a better prognosis.

Age group (yr)	Total (%)	Male (%)	Female (%)
All ages	8.2	8.2 (8.5 ^a)	8.1 (7.9 ^a)
<5	2.5	2.9	2.1
5-14	2.1	2.3	2.0
15-24	3.1	2.9	3.3
25-34	4.5	1.9	6.9
35-44	5.7	4.5	6.8
45-54	17.3	17.9	16.7
55-64	20.4	23.6	17.4
65-74	20.4	26.0	16.2
≥75	15.4	17.3	14.2

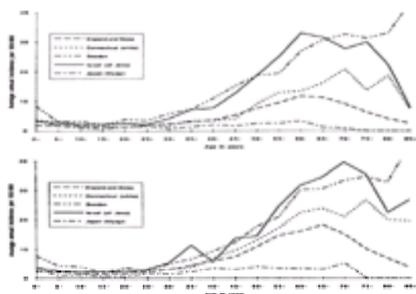

FIG. 52.1. Female (**top**) and male (**bottom**) age-specific incidence rates for malignant CNS tumors, 1978–1982. (From Muir et al.; with permission.)

Histologic diagnosis	Patients	
	Number	%
Glioma	7,940	57.8
Glioblastoma	2,740	20.0
Medulloblastoma	300	2.2
Cerebellar astrocytoma	120	0.9
Other astrocytomas and gliomas	4,780	34.8
Meningiomas	2,680	19.5
Neurinoma	940	6.9
Adenoma ^a	1,970	14.4
Other	190	1.4

^aIncludes 1,110 unconfirmed cases of pituitary neoplasms that are assumed to be adenomas. Modified from Walker et al., 1985.

TABLE 52.2. AVERAGE ANNUAL INCIDENCE OF PATHOLOGICALLY CONFIRMED INTRACRANIAL NEOPLASMS BY HISTOLOGIC DIAGNOSIS IN THE UNITED STATES, 1973 TO 1974

Epidemiologic reports of CNS tumors may be limited by several considerations: the histologic complexity of the tumors, lack of histologic verification in some cases, the retrospective nature of some studies, and the small number of patients in others. The possible effects of ethnicity, age, and sex may be distorted by unequal access to medical care or technology, as suggested by the variation in worldwide trends. It is possible that the increased incidence in the elderly may stem from the availability of CT in the 1970s and the introduction of stereotactic biopsy methods that are far less hazardous than diagnostic modalities employed earlier.

HISTORICAL PERSPECTIVE AND CLASSIFICATION

Although neurosurgical procedures were practiced as far back as the mesolithic period, it was Gallen (130 to 200 AD), Vesalius (1514 to 1564), and Willis (1621 to 1675) who laid the foundations for modern neuroanatomy. In the 19th century, neurology emerged as a discipline, cerebral localization was recognized, and the initial classifications of brain tumors appeared. In 1979, the World Health Organization formulated a classification of brain tumors that was based on the embryonal tissue of origin; this schema or its variations are currently used throughout the world. The current classification, based on conventional histologic features, is likely to be

modified in the future by molecular and genetic markers. For the purposes of this volume, we have classified brain tumors as follows:

Primary brain tumors

Glial tumors (see [Chapter 55](#))

Lymphomas (see [Chapter 56](#))

Pineal tumors (see [Chapter 57](#))

Meningeal neoplasms (see [Chapter 54](#))

Meningioma

Hemangiopericytoma

Tumors of the skull and cranial nerves (see [Chapter 53](#))

Spinal tumors (see [Chapter 62](#))

Extramedullary tumors

Intramedullary tumors

Intradural tumors

Vertebral tumors

Pituitary tumors (see [Chapter 58](#))

Metastatic tumors (see [Chapter 61](#))

Parenchymal metastases

Leptomeningeal metastases

Spinal cord metastases

Vascular tumors and malformations (see [Chapter 60](#))

Congenital and CNS tumors (see [Chapter 59](#))

BRAIN TUMOR BIOLOGY AND GENETICS

The developmental diversity of brain tumors could lead to specific therapies on the basis of cell lineage, stage of differentiation, and specific behavior. Several progenitor cells are recognized. One is a pluripotential cell that gives rise to both neuronal and microglial cell lines, as well as to tumors of either neuronal or glial types. Then, other forces play a role, including transcription and growth factors, matrix molecules, and proteases. Chromosomal aberrations in many primary brain tumors suggest a model of malignant progression. In this *multistep theory*, several genetic events are deemed necessary for the development of a brain tumor.

RISK FACTORS

Host Factors

Menopause, stroke, and breast cancer are host factors that may increase the risk for primary brain tumors. Family clustering is rarely seen, except sometimes in Mendelian patterns of inheritance. The increased risk of some occupations (e.g., electronics, pharmaceutical, and manufacturing industries) could reflect common exposure to an environmental agent or better access to medical care.

Environmental Factors

Studies of environmental factors have been inconclusive; many are conflicting. The environment may contribute one of several steps in the development of a brain tumor. *Chemicals* and *viruses* have been implicated. Chemical induction of CNS tumors has been found in animals given nitrosoureas, hydrazines, triazines, or aromatic hydrocarbons. Astrocytomas have appeared in patients with progressive multifocal leukoencephalopathy, in which cells are infected by the papovavirus JC virus. The Epstein-Barr virus has been identified in cells of primary CNS lymphoma; both adenovirus and SV-40 can induce tumors in laboratory animals. Studies of exposure to *electromagnetic fields* have not confirmed an increased incidence of brain tumors.

Ionizing *radiation* is a recognized risk factor. Moderate-dose irradiation of the scalp for tinea capitis in children increases the later risk of CNS tumors, particularly meningioma, glioma, and nerve sheath tumor. In adults, radiation to the head and dental x-rays have been associated with an increased risk for meningioma. An association with *diet* remains speculative; consumption of *N*-nitrous compounds in cured meats has been implicated, while the ingestion of antioxidants may be protective.

CLINICAL DIAGNOSIS

Symptoms and signs may be due to direct tumor effects and compression of adjacent structures, or to *secondary effects* of edema, hydrocephalus, or increased intracranial pressure (ICP). *Negative* symptoms arise from loss of function (sensory loss, weakness); *positive* symptoms include seizures or headache. Specific symptoms are more related to tumor *location* than to histology. Since the introduction of CT and magnetic resonance imaging (MRI), it is unusual to find tumors that lead to clinical symptoms after attaining a larger size, unless the tumor is located in a relatively silent area, such as the anterior frontal lobe or the nondominant temporal lobe ([Fig. 52.2](#)). Clinical manifestations are affected by the *rapidity* of tumor growth; slowly growing tumors may not be symptomatic because the adjacent brain may accommodate to the mass. Surrounding edema suggests rapid growth and may cause symptoms, even when the tumor is small.

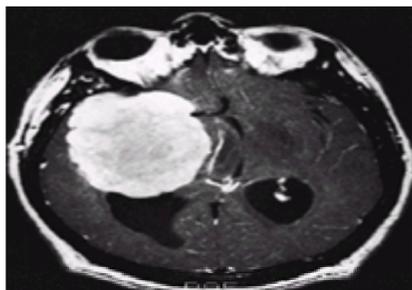

FIG. 52.2. Temporal meningioma (a large, slowly growing tumor affecting a “silent” area of the brain). This 38-year-old man had mild papilledema on routine eye examination. Gadolinium-enhanced MR image shows a 7-cm right temporal lobe meningioma.

Headache is the first symptom in 35% of patients and occurs later in 70%. Supratentorial tumors usually produce frontal headaches, while those in the posterior fossa lead to neck and occipital pain. Some characteristics raise suspicion of a primary tumor: morning headaches or those that waken the patient from sleep, improving later in the day; headaches that increase in frequency and severity in weeks or months; headaches that differ from a person’s pattern of chronic headaches; and, especially, headache associated with papilledema or focal cerebral signs. Pain is attributed to distortion of pain-sensitive structures in the intracranial compartment, such as the dura, venous sinuses, cerebral arteries, or the cranial nerves. Vomiting or nausea may be due to increased ICP or hydrocephalus. Involvement of the chemoreceptor trigger zone in the medulla may lead to *projectile* vomiting. Vomiting may terminate a headache because the hyperventilation that follows lowers ICP.

Facial pain may follow the distribution of the trigeminal nerve, with tumors at the base of the skull or nasopharynx. In contrast to trigeminal neuralgia, as tumor pain lasts longer, it is less likely to be lancinating and may be accompanied by sensory loss. *Temporal* or *auricular pain* may be seen with a thoracic malignancy, due to referred pain from irritation of the vagus nerve in the chest.

Plateau waves are periodic fluctuations of ICP. Typically, the elevation is abrupt, up to 100 mm Hg above baseline, and may be sustained for minutes or hours before quickly descending to normal. Clinically, the patient may have headache, nausea, vomiting, leg weakness, or other symptoms of incipient herniation. These waves

arise with severely increased pressure and are ominous. They may be triggered by cerebral vasodilatation caused by events that lower arterial blood pressure, such as infections, anesthetics, or rapid eye movement sleep. With severely increased ICP, one may observe a *Cushing reflex*, consisting of rising blood pressure and bradycardia. *Dizziness*, *vertigo*, and *hearing loss* may be seen in posterior fossa tumors.

Seizures are the first symptom in 30% of brain tumors and are present in up to 70% of patients at some time. Brain tumors, however, account for only 5% of all patients with epilepsy. Slowly growing tumors and those in the rolandic fissure tend to be the most epileptogenic. The association between brain tumors and seizures increases with age; most seizures in children arise from developmental conditions or injuries, while up to 20% of adults with new-onset seizures harbor a brain tumor. In adults, a first seizure, particularly if focal, should be evaluated by MRI for an occult brain neoplasm. If the first MRI is normal, a follow-up study is recommended. Seizure frequency varies with histology; seizures are seen in 37% of patients with glioblastomas, 65% to 70% with low-grade astrocytomas, and 75% to 95% with oligodendrogliomas. Seizures occur in only about 18% of patients with brain metastases.

Alterations in consciousness may be evident in 20% of patients at the time of diagnosis and vary from subtle personality changes to confusion or coma. The changes are most common with frontal lobe tumors, but they are also seen with hydrocephalus, gliomatosis cerebri, or brainstem compression from incipient herniation.

Focal Symptoms and Signs

Signs of brain tumors are more related to tumor location than to histology. The *temporal* pattern, such as a steadily progressive hemiparesis or aphasia, strongly suggests a neoplasm.

Frontal lobe tumors are initially silent; with time there may be personality changes, impaired judgment, abulia, gait abnormalities, urinary incontinence, gaze preferences, or primitive reflexes. *Temporal lobe* tumors tend to cause seizures that range from simple olfactory hallucinations, feelings of fear (sometimes misdiagnosed as anxiety attacks), or complex partial seizures. Temporal field cuts or aphasia may be present. *Parietal* tumors cause cortical sensory loss, neglect, anosognosia, hemiparesis, and disturbances of visuospatial abilities. *Occipital* tumors cause visual-field changes or, less commonly, visual seizures. *Thalamic* tumors lead to contralateral sensory loss, cognitive changes, and, rarely, aphasia. *Brainstem* tumors can cause cranial nerve disturbances, hiccups, vomiting, vertigo, and hemiparesis. Hydrocephalus may accompany thalamic or brainstem tumors. *Pineal* tumors cause signs and symptoms of hydrocephalus, Parinaud syndrome, or precocious puberty. *Intraventricular* tumors usually produce hydrocephalus. Valsalva maneuvers or postural change may worsen cerebrospinal fluid (CSF) flow, leading to headaches, weakness, or syncope. There may also be symptoms of hypothalamic or autonomic dysfunction, as well as memory problems. *Cerebellar* tumors can lead to headaches and ataxia. One may also find neck stiffness, vertigo, nystagmus, hypotonia, and cranial nerve or corticospinal tract signs.

Skull base tumors commonly affect cranial nerves. Meningioma of the olfactory groove causes anosmia. Optic nerve involvement by glioma or meningioma cause unilateral visual loss. Pituitary tumor causes bitemporal hemianopia from chiasmal involvement. Extraocular abnormalities can occur with cavernous sinus or brainstem tumors. Hearing loss and, less commonly, facial weakness can be seen with acoustic neuroma. Multiple cranial nerve signs are seen with carcinomatous meningitis, which can lead to the *numb chin syndrome* from involvement of the mandibular nerve.

False localizing signs may arise from increased ICP. The most common is a sixth nerve palsy produced by compression of the abducens nerve as it passes over the petrous ridge. The nerve is particularly vulnerable because of its long course. *Ipsilateral hemiparesis* may occur as a herniating uncus compresses the contralateral cerebral peduncle against the tentorium. Hydrocephalus may lead to gait abnormalities, bitemporal hemianopsia from chiasmal compression or, rarely, endocrine deficiencies from hypothalamic compression.

Cranial nerve palsies include *third nerve palsy*, which is usually ipsilateral when there is uncus herniation, but is sometimes contralateral. The pupillomotor fibers are the most superficially located, and a dilated pupil may be the first manifestation, a sign suggesting a compressive lesion. *Fourth nerve palsies* are rare but are also attributed to the long intracranial course of the nerve. Involvement of the *eighth nerve* may cause hearing loss or vestibular signs, including vertigo or nystagmus.

Neuroophthalmologic Signs

Oculomotor problems are common with tumors of the pineal area. The *Parinaud syndrome* consists of light-near dissociation, as well as paralysis of convergence and of upgaze. It is common with pineal tumors that compress adjacent midbrain. Pineal tumors can also lead to other disorders of ocular motility, such as convergence-retraction nystagmus, ptosis, or lid retraction (*Collier sign*). In children, a setting-sun sign is characteristic, consisting of downward deviation of the eyes and lid retraction.

Papilledema is rare as the first sign of tumor, as it follows sustained ICP elevations for weeks or months; it is secondary to transmission of increased ICP along the optic nerve sheath and to blockade of axoplasmic transport. Papilledema related to increased ICP is bilateral. Unilateral papilledema is due to asymmetric swelling of the optic nerve either because of the location of the lesion or because of a congenital anomaly that prevents one of the nerves from developing edema, with the nerve becoming atrophic. On visual-field testing, characteristic findings are enlargement of the blind spot and constriction of the visual fields ([Fig. 52.3](#)). The *Foster Kennedy syndrome*, consisting of ipsilateral optic nerve atrophy and contralateral papilledema, is usually associated with orbital or skull base tumors that compress the optic nerves. Asymmetric herniation may also occlude the posterior cerebral artery, leading to *homonymous hemianopsia* or *cortical blindness*.

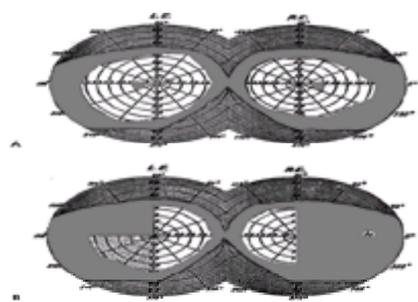

FIG. 52.3. Visual-field defects in intracranial tumors. **A:** Enlargement of blind spots and constriction of peripheral fields with increased ICP. **B:** Bitemporal hemianopia with pituitary adenoma. LABORATORY EXAMINATION

Plain Radiography

Skull x-rays are rarely obtained nowadays, but they may show calcification (oligodendroglioma, craniopharyngioma, and ependymoma), hyperostosis (meningioma), or bony erosion (pituitary tumors that erode the clinoid process). Spine radiography is rarely performed as a screening method for detecting metastatic disease or assessing the patency of a ventriculoperitoneal or ventriculothoracic shunt.

Computed Tomography

CT is widely used, better tolerated, less costly, and quicker to perform than MRI. CT is particularly useful in detecting calcification, the cranial bones, or intracerebral hemorrhage. Calcification is most common in slowly growing tumors. CT is less sensitive for small or posterior fossa tumors. Contrast administration is essential to visualize lesions hidden by an area of edema. CT is usually used to direct localization for a guided biopsy, but MRI technology for this is improving.

Magnetic Resonance Imaging

MRI is more sensitive than CT for delineating anatomic details and visualizing tumors in the brainstem or posterior fossa, as there is no bony artifact. MRI can detect solid and cystic components within a tumor and may show the relationship of the tumor to other intracranial structures. It allows visualization of the lesion in three planes (axial, coronal, and sagittal). Contrast administration detects defects in the blood–brain barrier (BBB) in many tumors and can be used for patients who are allergic to iodine or have renal failure. Furthermore, small lesions not seen on contrast-enhanced CT may be detected by MRI after the administration of gadolinium. Contrast studies are essential for some tumors, such as meningioma, which would otherwise not be visualized. Contrast enhancement on MRI performed within 48 hours of surgery is considered to be tumor, and not a postsurgical finding, which can be prominent and take several days to recede. MRI can be helpful in differentiating tumors from other intracerebral conditions, including brain abscess, which is characterized by a thin rim of enhancement, and cavernous angioma, which displays a characteristic target sign with a hypointense central area reflecting hemosiderin deposition. MRI of the spine has replaced myelography because it does not require a spinal tap, which may aggravate a spinal block in some metastatic cord tumors. Spine MRI with contrast can sometimes detect leptomeningeal tumor by enhancement.

Angiography

Angiography is used to define vascular anatomy before surgery (e.g., sphenoid-wing meningioma), to delineate the patency of the venous sinuses (e.g., falx meningioma), to exclude an arteriovenous malformation in some patients with intracranial hemorrhage, and to embolize vascular tumors preoperatively to reduce the size and facilitate resection. *MR angiography* or *MR venography* may reveal prominent blood vessels or sinus obstruction caused by a tumor.

Positron-emission Tomography

Positron-emission tomography (PET) using fluorodeoxyglucose tagged with fluorine 18 (^{18}F -FDG) is used to measure tumor metabolism and to try to differentiate tumor from radiation necrosis. Rapidly growing tumors have an increased glycolysis and cause increased ^{18}F -FDG; in contrast, areas of radiation necrosis show decreased glycolytic activity. PET can also detect decreased metabolic activity as tumors respond to chemotherapy. This technique can also be used therapeutically to perform radiolabeling of drugs or antitumor antibodies.

Single-photon Emission Computed Tomography

Single-photon emission computed tomography (SPECT) involves the administration of radioactive tracers that can be taken up by tumor cells. It may be useful in differentiating low-grade from high-grade gliomas and radiation necrosis from recurrent glioma. SPECT and the facilities necessary for it are less expensive than for PET, and it is widely available. *MR spectroscopy* may differentiate tumor from radiation necrosis.

Electroencephalography

Unilateral sharp waves on the electroencephalogram (EEG) may be the first indication of a focal lesion requiring further evaluation with imaging. The EEG should not be used as a screening test. Intraoperative EEG monitoring may also be useful if both seizure ablation and tumor resection are goals. In all unresponsive patients, EEG can rule out subclinical seizures or status epilepticus.

Evoked Potentials

Brainstem auditory evoked potentials may be abnormal in up to 96% of patients with acoustic neuroma; and visual evoked responses may be abnormal in tumors affecting the anterior visual pathways. These tests are most helpful for intraoperative monitoring during surgical resection.

Cerebrospinal Fluid Analysis

CSF analysis is not routinely performed because of possible herniation. The main indications for spinal tap are to investigate the possibility of leptomeningeal tumor or to exclude an infection. Lumbar puncture is useful in primary CNS lymphoma because identification of neoplastic cells in the CSF may obviate a biopsy of the tumor. It is also recommended in patients with germ cell tumors, as the CSF tumor markers beta-human chorionic gonadotropin and alpha-fetoprotein are essential for future management. In medulloblastoma and other primitive neuroectodermal tumors, the possibility of leptomeningeal tumor must be determined before treatment.

PHENOMENA ASSOCIATED WITH BRAIN TUMORS

Blood–Brain Barrier Disruption

The concept of the BBB emerged in the 19th century. The anatomic site of this barrier is considered to be the capillary endothelial cells. Normal cerebral capillaries are nonfenestrated, closed by tight junctions, and lack pinocytotic vesicles. In brain tumors, the BBB is disrupted, and the capillaries show defective tight junctions and fenestrations, increases in the pinocytotic vesicles, endothelial proliferation, and wide gap junctions. Permeability is mainly determined by the characteristics of the solute; lipid-soluble, low-molecular-weight, and nonprotein-bound or nonpolar substances cross more readily. Manipulation of the BBB may be important in brain tumor therapy.

Brain Edema

Tumor-associated edema is considered *vasogenic edema*, whose underlying mechanism is increased capillary permeability secondary to focal disruption of the BBB. Edema contributes to signs and symptoms, and ultimately may lead to increased ICP. It may be difficult to determine whether clinical deterioration is due to the edema or the tumor itself, but improvement after increasing or starting corticosteroids is a rough measure of the contribution of the edema. Radiographically, edema appears as fingerlike projections into the white matter that are bright on T2-weighted MR images. Corticosteroids may reduce the permeability of the disrupted BBB, alleviating the neurologic disorders due to edema and, possibly, allowing a safer surgical resection. Response occurs within hours, and neurologic signs can be completely reversed. Dexamethasone is most commonly used. Side effects of steroids should not be underestimated, and the lowest possible dose should be used. Other agents studied for control of vasogenic edema are the nonsteroidal antiinflammatory drugs.

Increased Intracranial Pressure

Increased ICP may be an inevitable consequence of brain tumors. Several mechanisms play a role: (1) additional mass in the fixed intracranial vault, (2) peritumoral edema, (3) intratumoral hemorrhage, or (4) obstruction of CSF pathways. The increased tumor volume is initially compensated by CSF displacement, increased absorption, and, possibly, decreased CSF production. With tumor growth, compliance decreases, and ICP starts to increase exponentially. At this time, the patient is extremely vulnerable, and any increase in blood volume superimposed on a noncompliant brain will significantly alter ICP and precipitate clinical deterioration, sometimes attributed erroneously to an intratumoral hemorrhage. As ICP continues to increase, there is loss of cerebral autoregulation and perfusion, and brain herniation is the end result. Treatment includes corticosteroids, mannitol (Osmitrol), and hyperventilation. A ventricular drain or ventriculoperitoneal shunt may need to be placed unless tumor removal achieves decompression. Seizure control is important, as seizure may aggravate ICP.

Vascular Effects

Brain tumors are responsible for about 5% of all intracranial hemorrhages. Up to 15% of all brain tumors have associated bleeding, mostly subclinical. The tendency to bleed depends on histologic subtype; metastases (melanoma, choriocarcinoma, and renal cell carcinoma) tend to bleed more often than primary brain tumors, among which glioblastoma (6.3%), mixed glioma and oligodendroglioma (8.3%), and choroid plexus papilloma (16.6%) have the highest bleeding tendency. Hemorrhage is usually intraparenchymal, into the necrotic area of the tumor. Subdural hematoma and subarachnoid hemorrhage are seen with meningioma. Structural abnormalities in the brain tumor vasculature is the mechanism implicated. The onset may be apoplectic or subacute. Clues to an underlying tumor include a history of prior headaches, seizures, mental status changes, or focal signs. Another warning sign is a hemorrhage that is not in a typical location for amyloid, hypertensive, or subarachnoid hemorrhages. Up to 15.8% of pituitary tumors may be associated with intratumoral hemorrhage or hemorrhagic infarction, termed

pituitary apoplexy. Embolic occlusion of cerebral vessels by tumor cells can lead to *hemorrhagic infarction*. Less commonly, brain tumors may mimic an *ischemic infarct*. Transient ischemic attack-like or strokelike syndromes may be seen in about 3% of patients, especially those with meningioma or a skull base tumor. A possible mechanism is direct vascular occlusion, vessel thrombosis and distal embolization, or arterial steal. A postradiation arteriopathy may occur months to years after radiation.

Hematologic Problems

Thromboembolic complications may be a risk of intracranial surgery, or may be related to the presence of the tumor itself. Autopsy studies show an 8.4% incidence of pulmonary embolism and up to a 27% incidence of deep vein thrombosis (DVT) in brain tumor patients, compared to the 17% incidence found in general neurosurgery patients. Glioblastoma has the highest incidence of DVT (60%), followed by meningioma (72%) and metastases (20%). The basis for enhanced thrombogenicity is not clear, but tumors may induce a prothrombotic state through the release of thrombogenic substances. Alternatively, patients may have coagulation abnormalities. Treatment includes intravenous heparin or placement of an inferior vena cava filter. Prophylaxis against DVT is imperative in the perioperative period, and it is necessary to have a very high index of suspicion at any point during the course of the disease. Hemangioma, and less commonly, meningioma, can be associated with *polycythemia*.

DIFFERENTIAL DIAGNOSIS

Despite the appropriate clinical scenario, many other conditions can mimic intracranial tumors. These include inflammatory conditions (*sarcoidosis, multiple sclerosis*), infections (*brain abscess, toxoplasmosis, cysticercosis, syphilitic gumma*), and vascular conditions (*intraparenchymal hematoma, acute stroke*). Stroke usually has an apoplectic presentation, compared to tumors, but hemorrhage into a tumor may mimic amyloid angiopathy or a hypertensive hemorrhage. Infiltrative tumors can also appear radiographically as infarcts. Lesions from multiple sclerosis may have transient contrast enhancement if they are acute. If the only radiographic abnormality is a single, contrast-enhancing lesion, then a biopsy or surgical resection is crucial for diagnosis. In most circumstances in which a brain tumor is a strong consideration, a biopsy or surgical resection of the lesion will identify the pathology, if all other tests are nonconclusive. In other circumstances, close clinical and radiographic follow-up is imperative because, rarely, patients previously considered to have a stroke whose condition worsens with time may have an occult tumor.

[Malignant Tumors Involving the Skull and Skull Base](#)
[Neoplastic-Like Lesions Affecting the Skull](#)
[Tumors of the Cranial Nerves](#)
[Suggested Readings](#)

BENIGN TUMORS OF THE SKULL

Osteoma

Osteoma is a benign growth of mature dense cortical bone, arising from either the outer or inner table of the skull. It often arises in the paranasal sinuses but may be found in the cranial vault, mandible, or mastoid sinuses. It has been associated with Gardner syndrome, an autosomal-dominant disorder that includes colonic polyps and soft tissue fibromas.

In most cases, the tumor is asymptomatic because it is slow-growing. In the paranasal sinuses, it may cause local pain, headaches, or recurrent sinusitis. Proptosis may result from growth into the orbit, although dural erosion with cerebrospinal fluid (CSF) rhinorrhea or direct brain compression is rare ([Fig. 53.1](#)). Mucoceles may be associated with osteomas that obstruct the frontal sinuses. In the calvarium, tumors are hard but painless, localized masses without much intracranial extension.

FIG. 53.1. Orbital osteoma. Coronal (A) and axial (B) CT with bone windows show an osteoma involving the orbit. The tumor, which had caused proptosis, was successfully resected.

Diagnosis is made on the characteristic radiographic appearance of a circumscribed homogeneous bone density best seen on computed tomography (CT) with bone windows. Symptomatic tumors are treated surgically, and reconstruction may be needed if the mass is extensive.

Chondroma

A chondroma is a rare, slow-growing benign tumor arising from the cartilaginous portion of bones formed by enchondral ossification. Since the bones of the cranial vault are formed by membranous ossification, chondromas are mainly limited to the skull base and paranasal sinuses. Lesions in the parasellar area or cerebellopontine angle often cause cranial nerve palsies. Radiographically, the tumors appear as lytic lesions with sharp margins and erosion of surrounding bone. Stippled calcification within the lesion helps distinguish it from a metastasis or chordoma. Treatment of symptomatic lesions is radical resection extending back to normal bone margins to prevent recurrence. Progression to a malignant chondrosarcoma is rare.

Hemangioma

Hemangioma is a benign vascular bone tumor comprising capillary or cavernous vascular channels. It is more common in the vertebral column than the cranial vault. Skull hemangioma varies from small, solitary lesions to huge lesions that receive blood from the scalp or meningeal vessels and may cause headache by periosteal involvement. Radiographically, a hemangioma creates an area of decreased density, often with a characteristic honeycomb or trabecular pattern. About 10% to 15% of lesions show the classic sunburst pattern of spicules radiating from a central point. On tangential views, the diploe is usually expanded, but the inner table is well preserved. Surgical resection is curative. Radiation therapy is sometimes recommended for incompletely resected or multiple tumors (particularly in the spine), but it is of uncertain efficacy.

Dermoid and Epidermoid Tumors

Dermoid and epidermoid tumors occur in the cranial vault, paranasal sinuses, orbit, and petrous bone. They are among the most common benign skull lesions in children. Radiographically, they produce rounded or ovoid lytic lesions with sharp sclerotic margins that involve all three layers of bone. Treatment is rarely indicated.

Other Benign Tumors of the Skull

An *aneurysmal bone cyst* is a lytic lesion composed of large vascular spaces separated by trabeculae of connective tissue and bone. Although much more commonly found in the shaft of long bones, it can also cause painful swelling in the cranial vault. *Ossifying* and *nonossifying fibromas*, *osteoid osteoma*, and *osteoblastoma* are related tumors that contain varying degrees of fibrous tissue and mature bone. *Giant cell tumors* are composed of giant cells interspersed with indistinct stromal cells; they create in well demarcated areas of bony erosion. The clinical behavior of giant cell tumors varies; some are aggressive and malignant. As with most other benign tumors of the skull, these are best viewed on CT with bone windows. Magnetic resonance imaging (MRI) may help detail intracranial extension. Treatment is surgical resection.

MALIGNANT TUMORS INVOLVING THE SKULL AND SKULL BASE

Metastasis to the Skull Base

The cranial nerves exiting through the bony foramina are vulnerable to entrapment and compression by tumors that extend from osseous metastasis. This situation is most likely to be seen in patients with tumors of breast, lung, prostate, or the head and neck, or with lymphoma. Localized cranial or facial pain at the site of tumor invasion is attended by signs of cranial neuropathy. The pain is usually progressive, but the cranial neuropathy may appear during the course of a single day ([Table 53.1](#)).

Syndromes	Symptoms	Common syndromes (cranial nerves affected)
Ocular	Proptosis, diplopia, facial numbness	Abducens (VI), optic (II)
Trigeminal	Diplopia, facial numbness	Facial (V), abducens (VI), optic (II)
Paranasal	Facial pain, diplopia	Olfactory (I), II
Middle fossa or parasellar ganglion	Facial pain, trigeminal sensory loss, trigeminal neuralgia	Vermis (IX, X, XI)
Angular trismus	Headaches, hyperkalemia, glossopharyngeal neuralgia	Cerebellum (IX, X, XI)
Occipital condyle or hypoglossal canal	Dysarthria, hypoglossal, and accessory nerve palsy	VIII (I, II, III, IV, V, VI, VII, VIII, IX, X, XI, XII)
Vertical nerve trismus	Number of sites with or without pain	Acoustic neuroma

TABLE 53.1. CLINICAL SYNDROMES ASSOCIATED WITH METASTASES TO THE BASE OF THE SKULL

Coronal- and axial-plane CT with appropriate adjustment of bone windows can visualize bony structure. MRI is becoming increasingly sensitive for small lesions. Erosion is not always seen on CT, and many metastatic tumors cannot be verified radiographically. When the clinical picture is clear and symptoms are progressive, it may be necessary to treat without radiographic documentation. Biopsy is difficult and hazardous, even with stereotactic approaches.

The most important differential diagnosis is meningeal carcinomatosis; therefore examination of CSF cytology is crucial. In meningeal carcinomatosis, pain is usually less prominent, and other sites are affected, especially spinal cord or nerve roots. Occasionally, meningeal carcinomatosis accompanies metastasis to the base of the brain.

Palliative treatment is recommended with radiotherapy dosages of at least 3,000 cGy given to the affected areas in 300-cGy fractions. Although palliation of symptoms is fairly good (86%), early treatment (within 1 month of onset of symptoms) is effective in 92% of patients; after 1 month, the figure drops to 78%.

Extension of Malignant Tumors to the Skull Base

Several malignant tumors involve the base of the skull by direct extension (Fig. 53.2). These include squamous cell carcinoma (nasal sinuses and temporal bone), adenoid cystic carcinoma (salivary glands), esthesioneuroblastoma (olfactory mucosa), and nasopharyngeal carcinoma. These tumors cause pain and involve the cranial nerves. Erosion of the skull base or the presence of a soft tissue mass may be seen on CT or MRI; biopsy is often diagnostic. Small tumors diagnosed before invasion of sensitive neural structures can sometimes be cured with wide surgical excision. Most tumors are more extensive when detected, and despite treatment with radical excision and radiation therapy, the prognosis is often poor.

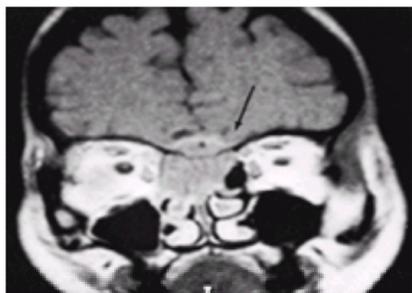

FIG. 53.2. Esthesioneuroblastoma. Coronal MR image demonstrates an esthesioneuroblastoma in the ethmoid sinus with intradural extension (arrow). This tumor arises from the olfactory mucosa.

Primary Malignant Tumors of the Skull

Chondrosarcoma is a malignant cartilage tumor originating in the enchondral bones of the skull base. It is most common in men during the fourth decade and often found in the parasellar areas, cerebellopontine angle, and paranasal sinuses. Chordoma is a tumor derived from primitive notochordal tissue and tends to arise from either end of the vertebral column. Intracranial chordoma often extends from the clivus into the middle fossa or brainstem. It is a locally invasive tumor that destroys the surrounding skull base; however, it rarely metastasizes.

Osteogenic sarcoma (osteosarcoma) is the most common primary malignant bone tumor, most frequently seen in the second decade of life (Fig. 53.3). There may be an association between osteogenic sarcoma and prior radiation, Paget disease, fibrous dysplasia, or chronic osteomyelitis. This tumor has a particularly poor prognosis.

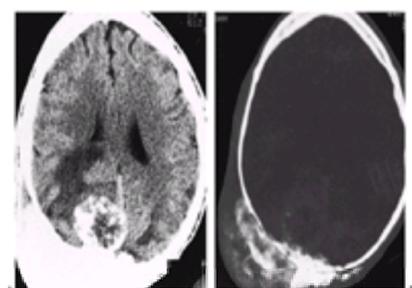

FIG. 53.3. Osteosarcoma. **A:** Noncontrast axial CT shows a calcified mass within the medial right parietooccipital lobes with massive extracranial soft tissue swelling. **B:** Corresponding bone window view shows thinning and erosive changes of calvarium with several large areas of calcification and ossification within extracranial soft tissues in the right parietooccipital region. These findings are classic for osteosarcoma, and the lesion was surgically proved.

Fibrous sarcoma is a soft tissue tumor that arises from bone, periosteum, scalp, or dura. It is often accompanied by bony destruction, showing a regular but discrete lytic radiographic picture.

Treatment for all of these malignant tumors is radical surgical resection with extensive margins. Metastatic workup is routine in these patients. Surgery is often difficult for lesions at the base of the skull. Radiotherapy is usually given as adjunctive therapy, but it is of questionable value. Charged-particle irradiation, such as proton beam or helium, is particularly effective for chordoma or chondrosarcoma of the skull base.

Glomus Jugulare Tumors

Tumors of the glomus jugulare arise from chromaffin cells in the region of the jugular bulb and invade the neighboring temporal or occipital bones. They are locally invasive, although metastasis is rare. They may extend into the middle ear and posterior fossa to cause tinnitus, an audible bruit, deafness, and lower cranial neuropathies. Larger tumors may cause cerebellar and brainstem symptoms. Occasionally, they are discovered as small vascular masses protruding into the middle ear cavity. The differential diagnosis includes neurinoma, cholesteatoma, chondrosarcoma, carcinoma, metastatic tumor, and meningioma. The tumors are visualized by MRI or CT with contrast and confirmed angiographically. These tumors are highly vascular, and embolization may be palliative or used preoperatively to facilitate surgery. Surgery offers the best chance of cure or extended control of the disease. Radiation therapy may be beneficial, although responsiveness is difficult to evaluate.

NEOPLASTIC-LIKE LESIONS AFFECTING THE SKULL

Hyperostosis

Although local overgrowth of the skull bones may be secondary to intracranial tumors, such as meningioma, it may occur without any tumor. Hyperostosis of nonneoplastic etiology may involve either the outer or inner table of the skull. Outer-table involvement is insignificant, except for disfigurement from extensive growth. Hyperostosis of the inner table is rarely of sufficient size to compress intracranial contents. Hyperostosis of the inner table of the frontal bone (*hyperostosis frontalis interna*) is a common asymptomatic finding, particularly in routine radiographs of middle-aged or elderly women. Attempts have been made to associate these changes in the skull with headaches and other somatic symptoms common at the time of menopause, but this seems unlikely because hyperostosis is so often asymptomatic.

Fibrous Dysplasia

Fibrous dysplasia is more common in men and rarely occurs after age 40 years ([Fig. 53.4](#)). Localized involvement of the skull base and sphenoid wing, particularly by the sclerotic variety, may become symptomatic by compressing the contents of the foramina at the skull base. Nerve decompression is usually effective treatment because the process is rarely progressive. The etiology of fibrous dysplasia is unknown.

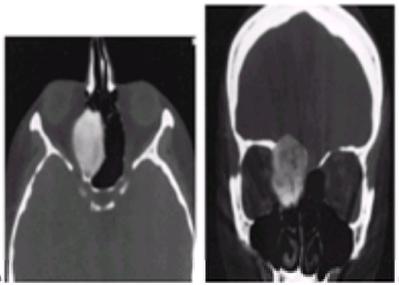

FIG. 53.4. Fibrous dysplasia. Axial (A) and coronal (B) CT with bone windows demonstrates fibrous dysplasia of the orbit and ethmoid sinus. This lesion was cured by surgical resection.

Paget Disease

Paget disease (*osteitis deformans*) is usually a multicentric disease that frequently involves the skull. Skull x-rays show a characteristic diffuse, mottled thickening of the cranial vaults and often discrete lytic lesions. Pain is the most frequent symptom. Any of the neural foramina of the skull base may be compromised, but visual and hearing loss are the most common symptoms.

Mucocele

Obstruction of a nasal sinus ostium may result in an encapsulated thick fluid collection known as a mucocele ([Fig. 53.5](#)). Mucoceles may erode through the base of the skull and result in intracranial compression. Surgery with reconstruction is the treatment of choice.

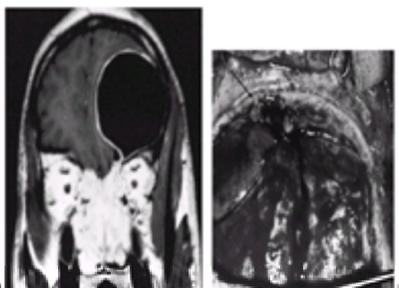

FIG. 53.5. A: Frontal mucocele. **A:** Coronal MRI with contrast enhancement shows a large mucocele compressing the frontal lobe, with chronic inflammation of the nasal mucosa obstructing the nasal sinuses. **B:** Intraoperative photograph shows the mucocele before its resection and subsequent reconstruction of the cranial base defect. The frontal sinus contains inflammatory tissue (*arrow*), which had caused obstruction of the sinus.

Miscellaneous Diseases Involving the Skull

Systemic diseases may involve the skull. These include xanthomatosis (Hand-Schöller-Christian disease), multiple myeloma, and osteitis fibrosa cystica. The symptoms and signs of these conditions are considered in detail elsewhere.

Other disorders that simulate skull tumors include leptomeningeal cysts (growing skull fractures), sinus pericranii, metabolic diseases such as hyperparathyroidism and acromegaly, infections, sarcoidosis and histiocytosis X. Neuroectodermal dysplasia commonly involves the cranial bones, as well.

TUMORS OF THE CRANIAL NERVES

Neurinomas overwhelmingly involve sensory nerves; the eighth cranial nerve is the most common site and the fifth nerve a distant second. Among motor nerves, the seventh is most commonly affected. Ninth, tenth, and twelfth nerve neurinomas occur but are rare, except in von Recklinghausen disease. Neurinomas are generally firm, encapsulated, and circumscribed, well-suited for surgical resection if symptomatic. Surgical resection usually requires sacrifice of the involved nerve root.

Trigeminal Neurinoma

Trigeminal neurinomas are rare and originate along a root or ganglion or, less commonly, in a proximal division of the trigeminal nerve. Nearly all patients note numbness and pain in the trigeminal distribution. Fewer than 50% of patients note mild weakness in chewing. True trigeminal neuralgia is exceptional. Extension of the tumor into the posterior fossa is associated with seventh and eighth nerve dysfunction and cerebellar and pyramidal tract signs. About 50% of these tumors are limited to the middle fossa, while others extend into the posterior fossa. CT with bone windows may demonstrate erosion of the petrous apex, foramen ovale, or foramen rotundum (Fig. 53.6). The differential diagnosis includes meningioma, acoustic neuroma, epidermoid lesions, and primary bone tumors of the skull base. Surgical resection is highly successful in providing cure or long-term control of the tumor.

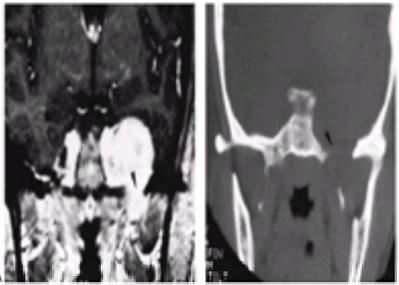

FIG. 53.6. Trigeminal neuroma. **A:** Coronal gadolinium-enhanced MRI shows a trigeminal neuroma that has extended through the foramen ovale (*arrowhead*). **B:** Coronal CT with bone windows shows the widening of the foramen ovale by the tumor (*arrowhead*).

Acoustic Neuroma

Acoustic neuroma (acoustic neurinoma, acoustic neurofibroma) is a benign tumor arising from Schwann cells of the vestibular branch; it is actually a vestibular schwannoma. Acoustic neuroma accounts for 5% to 10% of all intracranial tumors and is the most common tumor of the cerebellopontine angle. It is found equally in men and women at an average age of around 50. Bilateral tumors occur in less than 5% of patients and are associated with neurofibromatosis in young patients (Fig. 53.7).

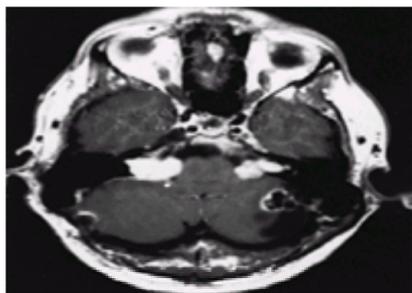

FIG. 53.7. Bilateral acoustic schwannomas. T1-weighted axial MR scan after gadolinium administration shows enhancing masses within both cerebellopontine angles and internal auditory canals, most consistent with bilateral acoustic schwannomas. (Courtesy of Dr. S. Chan, Columbia University College of Physicians and Surgeons, New York, NY.)

An acoustic neuroma grows off of the vestibular nerve, usually at the level of the porus acusticus, extending into both the internal auditory meatus and the cerebellopontine angle, where it displaces adjacent neural structures, cerebellum, pons, and cranial nerves VII and VIII. Although growth rates vary, most acoustic neuromas grow slowly at 2 to 10 mm per year; many are large and even cystic before they become symptomatic. The growth rate may increase during pregnancy.

Macroscopically, a neuroma is usually yellowish, sometimes with areas of cystic degeneration. Microscopically, there are two main patterns: Antoni A type, with cells forming compact bands of elongated elements, often simulating a palisade effect; and Antoni B type, with a looser pattern of stellate cells with long irregular processes.

Increased clinical awareness and more sophisticated radiographic techniques, such as MRI, have allowed earlier detection, so that the clinical picture has changed in the last decade (Table 53.2). Gradually, progressive unilateral hearing loss occurs in nearly all patients. Actual hearing loss is often preceded by difficulty with speech discrimination, especially when the patient is talking on the telephone. Tinnitus (70%) and unsteady gait (70%) are common. Patients sometimes note true vertigo, but typical Meniere syndrome is rare. Further growth can cause facial numbness or, less often, facial weakness, loss of taste, and otalgia. Paroxysmal trigeminal pain is rare. Larger tumors may cause headache, nausea, vomiting, diplopia, and ataxia, or symptoms of increased intracranial pressure and hydrocephalus. Other signs include tinnitus, nystagmus, facial weakness, and decreased sensation in the trigeminal distribution with a decreased corneal reflex. Larger tumors may cause altered eye movements, cerebellar and pyramidal signs, and papilledema, or they may compromise the lower cranial nerves.

	%		%
Hearing loss	97	Decreased corneal reflex	37
Dysequilibrium	70	Nystagmus	34
Tinnitus	70	Facial hypesthesia	29
Headache	38	Abnormal eye movement	14
Facial numbness	33	Facial weakness	13
Nausea	13	Papilledema	12
Otalgia	11	Babinski sign	8
Diplopia	9		
Facial palsy	9		
Loss of taste	9

TABLE 53.2. SYMPTOMS AND SIGNS IN 76 PATIENTS WITH SURGICALLY CONFIRMED ACOUSTIC NEUROMA

Gadolinium-enhanced MRI is the best way to demonstrate an acoustic neuroma (Fig. 53.8). CT with contrast demonstrates nearly all tumors greater than 1.5 cm. On rare occasions, installation of air or water-soluble dye with CT may demonstrate a tumor that is only equivocal on MRI studies (Fig. 53.9). An acoustic neuroma growing in the internal auditory canal or meatus causes erosion of the superior margin of the canal or asymmetric widening of the canal, which can best be appreciated on CT with bone windows. Other radiographic signs include widening of the ipsilateral pontine cistern, deviation of the fourth ventricle, or hydrocephalus.

Angiography is rarely necessary.

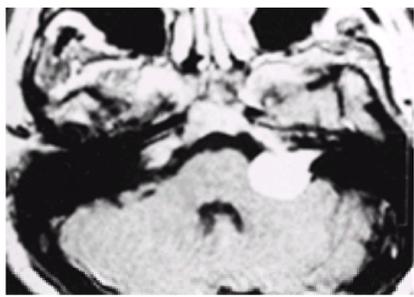

FIG. 53.8. Acoustic neuroma. T1-weighted axial MRI with gadolinium shows an acoustic neuroma with flaring of the internal auditory canal.

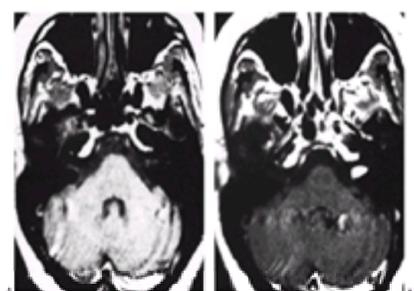

FIG. 53.9. Intracanalicular acoustic schwannoma. **A:** T1-weighted axial MR image before contrast administration shows no definite mass within the internal auditory canals. **B:** With gadolinium, there is clear-cut contrast enhancement within the left internal auditory canal, most consistent with intracanalicular acoustic schwannoma. (Courtesy of Dr. S. Chan, Columbia University College of Physicians and Surgeons, New York, NY.)

Brainstem auditory evoked potentials responses are abnormal in 98% of acoustic tumors. Caloric stimulation with electronystagmography is a sensitive test but is of limited usefulness because it does not discriminate between inner ear abnormalities and eighth nerve dysfunction and may be normal, even in the presence of a tumor. Nearly all patients have pure tone abnormalities on audiometry. Most commonly, there is high-frequency hearing loss with impaired speech discrimination.

The clinical picture of an acoustic neuroma can be simulated by any mass in the cerebellopontine angle, including neuromas of the fifth or other cranial nerves, meningioma, cholesteatoma, choroid plexus papilloma, glioma, cysts, and aneurysms.

Surgery using microsurgical techniques is usually curative. Facial nerve function can be preserved in more than 95% of patients with small tumors (less than 2 cm) and more than 80% of patients with medium tumors (2 to 3 cm), but in fewer with large tumors. If useful hearing was present preoperatively, hearing may be preserved in tumors smaller than 2 cm in diameter. Because of the relatively slow growth of these tumors, a subtotal resection or conservative treatment may be indicated in elderly patients with minimal symptoms. Radiosurgery may reduce or arrest the growth of acoustic neuromas, particularly in poor-risk patients with tumors smaller than 3 cm in diameter. Long-term follow-up after radiosurgery has not been available, and careful microsurgical technique is currently the preferred treatment because of its low morbidity and nearly absent mortality rate.

CHAPTER 54. TUMORS OF THE MENINGES

CASILDA M. BALMACEDA, MICHAEL B. SISTI AND JEFFREY N. BRUCE

[Etiology](#)
[Biology](#)
[Pathology](#)
[Clinical Manifestations](#)
[Imaging](#)
[Treatment](#)
[Suggested Readings](#)

Meningiomas originate in the arachnoid coverings of the brain. They account for 20% of all intracranial tumors in men, and 38% of those in women, occurring in 2 per 100,000 people. These figures may be low because asymptomatic tumors are not included. Age at diagnosis is in the sixth or seventh decades. The frequency in women is twice that in men; spinal meningiomas occur 10 times more often in women. Meningiomas account for about 7% of all posterior cranial fossa tumors and 3% to 12% of cerebellopontine angle tumors. They are rare in children; in childhood there is a male predominance, and the tumors rarely have a dural attachment, are more common in the posterior fossa or at intraventricular sites, and commonly show sarcomatous changes that render surgical resection difficult. In children, meningiomas are frequently associated with neurofibromatosis. Multiple meningiomas occur in 5% to 15% of patients, especially those with neurofibromatosis. More than 90% of tumors are intracranial and 10% intraspinal.

ETIOLOGY

Some exogenous factors have been implicated in the etiology of meningiomas. Low-dose *radiation* was formerly used to treat children for tinea capitis of the scalp; 10 to 20 years later the incidence of meningiomas was four times higher in the irradiated group than in the nonirradiated group. Dental radiographs and radiation therapy for intracranial tumors have also been considered risk factors. After low-dose irradiation for nonneoplastic conditions, meningiomas may appear after an average latency of 36 years; after higher-dose irradiation for preexisting tumors, they appear as early as 5 years later (mean, 24 years; range, 5 to 40 years). Radiation-induced tumors tend to occur over the convexities, are more likely to be multiple and histologically malignant, and are more likely to recur. *Head trauma* has not been confirmed as a risk factor by epidemiologic studies.

Endogenous stimulation via *hormones* may play a role in etiology. Estrogen and progesterone have been implicated because of the higher rate for meningiomas in women, an apparent association with breast cancer, and the frequent increase in size of the tumor during pregnancy. Estrogen receptors are marginally present in meningiomas; binding occurs to a type II receptor that does not have as much affinity for estrogen as the receptor found in breast carcinomas. In contrast, the progesterone receptor is expressed in about 80% of women and 40% of men with meningiomas, and binding is seen in 50% to 100% of specimens. Binding sites for progesterone are less common in aggressive meningiomas. *In vitro* growth studies with progesterone are variable. Androgen receptor studies are still preliminary, but antiandrogens inhibit cultured meningioma growth. The relationship between the presence or absence of receptors and the effect of the ligand is not well understood, particularly because most receptors are located in the cytosol and not in the nucleus.

Viral antigens in meningiomas suggest a role in either tumor induction or maintenance, but not necessarily a causal relationship. Meningiomas are thought to arise through a multistep process involving both oncogene activation and loss of tumor suppressor genes. *Molecular genetics* has shown several alterations, most commonly loss of the long arm of chromosome 22 in 80% of all meningiomas. A tumor suppressor gene has been implicated because chromosome 22 also hosts the NF2 gene, absent in neurofibromatosis and mutated in many meningiomas. Almost all familial meningiomas occur with NF2; likewise, patients with type II neurofibromatosis (NF) are at increased risk for meningioma. The location of the *c-sis* protooncogene (a polypeptide homologous with platelet-derived growth factor [PDGF] receptor) on chromosome 22 strengthens the putative role of chromosome 22 in meningioma biology. Abnormalities have also been observed in other chromosomes, suggesting that there are several oncogenes or tumor suppressor genes.

BIOLOGY

With a paucity of animal models, most studies have used cell cultures. Several *growth factor* receptors expressed include those for epidermal growth factor (EGF), PDGF, insulin-like growth factors, transforming growth factor- β , and somatostatin, all of which increase meningioma cell proliferation. EGF is inhibited by interferon; clinical trials are in progress. *Angiogenesis* is of interest for potential therapy. Meningiomas contain vascular endothelial growth factor, but it seems to be confined to the stroma, not the meningioma cells themselves. PDGF and fibroblast growth factor are also angiogenic. *Proteolysis* may be involved. High levels of proteases are associated with more efficient invasion; a balance between the proteases and their inhibitors determines the infiltrative capacity.

PATHOLOGY

Meningiomas are thought to arise from the meningothelial cap cells that are normally distributed through the arachnoid trabeculations. The highest concentration of meningothelial cells are found in the arachnoid villi at dural sinuses, cranial nerve foramina, middle cranial fossa, and the cribriform plate. On *gross examination*, the tumors are nodular and compress adjacent structures. Occasionally, they are distributed in sheathlike formations (*meningioma en plaque*), especially at the sphenoid ridge. The tumors are encapsulated and attach to the dura, which provides blood supply; there may be adjacent hyperostosis. *Microscopically*, meningiomas appear histologically benign. There is no characteristic cytologic marker, and diagnosis is based on the typical features: whorls of arachnoid cells surrounding a central hyaline material that eventually calcifies to form psammoma bodies. Cells are arranged in sheaths separated by connective tissue trabeculae.

A widely used classification describes the tumors as meningotheliomatous (syncytial), fibrous, transitional, or psammomatous, but this division has little prognostic value. The World Health Organization grading system classifies tumors as *typical* or *benign*, *atypical*, or *malignant* on the basis of cellularity, mitosis, necrosis, and brain invasion. About 3% of "benign" meningiomas and 78% of the "atypical" tumors recur in 5 years. Median time to recurrence for benign lesions is 7.5 years and for malignant 3.5 years. *Malignant meningiomas* are rare, accounting for about 12% of such tumors. They invade both brain and dura, making surgical removal difficult. Systemic metastases occur in 24% of patients, usually to bone or lung. These tumors are not amenable to hormonal therapy. *Papillary* and *angioblastic* meningiomas are aggressive and have an increased incidence of metastases.

Hemangiopericytomas are meningothelial tumors that are derived not from meningothelial cells but from the pericytes, smooth muscle cells associated with small blood vessels. They were formerly considered angioblastic meningiomas, but ultrastructural studies revealed their distinct origin. They most often occur in the extremities, head and neck, and pelvis but may be found near the meninges. They account for up to 7% of all meningeal tumors and are highly aggressive, the incidence of recurrence varying from 26% to 80%. Survival rates of 44 to 68 months have been reported after surgery with or without postoperative radiotherapy, respectively. Up to 23% of hemangiopericytomas in the CNS metastasize, most often to bone, liver, or lung. Surgical excision is the most common therapy, and postoperative irradiation to doses greater than 55 Gy has led to a significantly improved relapse-free survival; however, recurrences are invariable despite irradiation.

CLINICAL MANIFESTATIONS

Meningiomas may be asymptomatic and found incidentally on magnetic resonance imaging (MRI). Neurologic disability is often due to tumor location rather than the histologic features. Local secondary effects include brain compression, edema, or destruction, or cerebral cortex invasion and hyperostosis. Symptoms include many years of seizures, visual problems, hemiparesis, cranial nerve dysfunction, or increased intracranial pressure.

IMAGING

Skull *x-rays* of a convexity meningioma may show calcification, hyperostosis, or enlargement of the vascular channels. On computed tomography (CT), the tumor appears isointense or slightly hyperdense, compared with the brain. The mass is smooth and sometimes lobulated, and may be calcified. Enhancement is strong and homogeneous. If calcification is dense, enhancement may not be evident. Margins are distinct, and the tumor seems to arise from the dura. Edema is common, appearing hypointense compared with the brain. Hyperostosis is seen in 25% of patients.

On *MRI*, the tumor is isointense (65%) or hypointense (35%), compared with the gray matter, on T1-weighted imaging, as well as on T2-weighted imaging. Enhancement with gadolinium is intense and homogeneous (Fig. 54.1). There may be a *dural tail* of attachment, which may also be seen in acoustic neuroma or dural metastasis. MRI shows the relationship of the tumor to the brainstem, cranial nerves, and blood vessels.

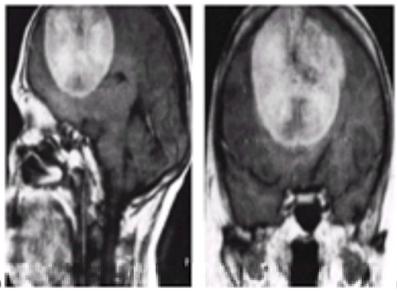

FIG. 54.1. Parasagittal falx meningioma. Sagittal (A) and coronal (B) T1-weighted contrast-enhanced MR images show an enormous tumor arising from the falx.

Angiography may show a relationship to blood vessels. The typical appearance is a mass with a blush. The venous phase can assess flow in the sinuses (which may be compressed or thrombosed by tumor), internal jugular vein, and the vein of Labbé. Angiography is not performed unless preoperative embolization is planned to reduce the risk of intraoperative bleeding, *MR angiography* may ultimately replace intraarterial injections.

Atypical radiographic features in about 15% of meningiomas include cysts, hemorrhage, and necrosis, which mimic gliomas. It may be difficult to distinguish intraaxial and extraaxial superficial lesions. CT or MRI may help identify the two types of intracranial lesions seen in patients with breast cancer: dural metastasis and meningioma. Metastases are commonly associated with abundant surrounding edema and bone destruction; in contrast, hyperostosis and moderate edema suggest meningioma. Malignant meningiomas commonly show bone destruction, areas of necrosis, irregular enhancement, or projection toward the brain. Other imaging features, such as location or invasion of surrounding structures, are more likely to predict the clinical course.

TREATMENT

Surgery

Surgery can reverse most meningiomas, which are potentially curable. Factors that influence the type of surgery include location, preoperative cranial nerve deficits (for posterior fossa meningiomas), vascularity, invasion of venous sinuses, and encasement of arteries. Partial resection is an option if the patient is asymptomatic and total tumor removal may risk an unacceptable loss of function.

In convexity meningiomas, the dura is resected to decrease the chances of recurrence. If venous sinuses are totally occluded or thrombosed, the involved segment can be resected without influencing flow. Meningiomas of the medial sphenoid wing, orbit, sagittal sinus, cerebral ventricles, cerebellopontine angle, optic nerve sheath, or clivus may be difficult to remove entirely. For cavernous sinus meningiomas, the risk of injury to cranial nerves or internal carotid artery is a concern, and surgical cure may not be feasible.

Surgery can reverse most neurologic signs. Operative morbidity ranges from 1% to 14%. The extent of resection is the most important factor in determining recurrence. After complete resection, the estimated 10-year survival ranges from 43% to 77%. At 10 years, the recurrence rate for completely resected tumors is 9% and for subtotal resection 40%. New techniques include computerized virtual reality, a three-dimensional reconstruction of the brain that assists the surgeon in planning the procedure; it is an invaluable technique in establishing the relationship of the tumor to brainstem, vessels, or cranial nerves. Intraoperative MRI shows real-time images during surgery.

Preoperative *embolization* is performed to decrease tumor vascularity, facilitate removal, and decrease blood loss. Embolization of the dural tail may decrease recurrences. The procedure is not routinely done either because most centers lack embolization personnel or because small lesions can be removed without much blood loss.

Radiation Therapy

Currently, accepted indications for radiation include residual tumor after surgery, particularly in a young patient; recurrent tumor; or malignant histology. Radiotherapy has rarely been used for primary therapy if the tumor is inaccessible or there is a medical contraindication to surgery. The 10-year local control rate for combined subtotal resection and radiation is 82% compared to 18% for subtotal resection alone. Time to recurrence was 125 months for irradiation and 66 months for resection without irradiation after subtotal resection. For malignant meningiomas, overall 5-year survival after surgery and radiation is 28%. The recurrence rate for malignant meningiomas is 90% after subtotal resection and 41% after resection plus radiation.

The *proton beam* delivers heavy charged particles; it may be more effective for deep therapy and may minimize damage to normal tissue in brainstem meningiomas. Because of the long survival of patients with benign meningiomas, radiation-induced secondary tumors are a concern. *Radiosurgery* involves focused radiation given in one large dose in an attempt to minimize damage to adjacent structures. Radiosurgery is done with a linear accelerator or gamma rays as sources of energy. Black and colleagues (1997) treated skull base meningiomas with radiosurgery; after 5 years, 41% of tumors had decreased in size, 54% remained stable, and 5% continued to grow. Reversible brainstem edema or permanent cranial nerve symptoms developed in 5 of 56 patients. Another approach is stereotactic radiotherapy, in which radiation is given in multiple small fractions for optic nerve tumors, cavernous sinus meningiomas, or tumors close to the brainstem in an effort to avoid the ill effects of single large doses. With this method, 71% of the patients survived for 5 years; 72% of symptomatic patients showed neurologic improvement, particularly those with cavernous sinus meningiomas. This supports the use subtotal resection plus radiation for these tumors.

Medical Treatment

Hormonal Treatment

Antiandrogen therapy has been ineffective. Mifepristone (RU-486), an antiprogestone agent, has five times the affinity of progesterone, crosses the blood-brain barrier, and binds to androgen and antiglucocorticoid receptors. A size decrease in one-third of recurrent meningiomas with RU-486 has been reported, and the drug is now in clinical trial.

Chemotherapy

A last resort for patients with a recurrent meningioma who have undergone multiple resections and maximum irradiation is chemotherapy. Experience is limited, and no agent has been visibly effective. On the premise that meningiomas are of mesenchymal origin, agents such as ifosfamide (used for systemic sarcomas) are being studied for the treatment of malignant meningiomas.

Supportive Treatment

Because of side effects, corticosteroid therapy is avoided unless absolutely necessary. Prophylactic anticonvulsant therapy is also controversial. As with other brain tumors, thromboembolism is a hazard, warranting the use of antiembolic stockings, subcutaneous heparin, and early postoperative mobilization. Some experts

advocate observation of tumors if they appear radiographically to be typical meningiomas and are small and asymptomatic, especially in patients older than 60 years. Among 57 patients with asymptomatic meningiomas, no patient experienced symptoms after being followed radiographically for an average of 32 months. The average growth rate was 0.24 cm per year.

Specific Tumor Locations

Convexity Meningiomas

Convexity meningiomas are the most amenable to surgical cure because wide dural margins can be resected (Fig. 54.2). If the tumor invades an eloquent area of the brain, complete resection may not be feasible. *Parasagittal* meningiomas tend to involve the superior sagittal sinus. If the sinus is patent, a subtotal resection may prevent occlusion and venous infarction. *Olfactory groove* meningiomas with invasion of the frontal sinuses usually require a bifrontal craniotomy. Piecemeal resection may preserve the optic nerves. *Tuberculum sellae* meningiomas usually cause visual loss, anosmia, headache, or hypopituitarism. Up to 42% of patients have visual improvement after surgery, 30% do not change, and 28% become worse. Meningiomas can occur within the sella region, originating from the diaphragma sellae. Radiographic evidence of sellar enlargement or calcification may help differentiate the tumor from a pituitary adenoma. *Optic sheath* meningiomas are difficult to resect, and surgery is reserved for patients with visual loss. Radiation may slow the growth of tumors that do not yet affect vision.

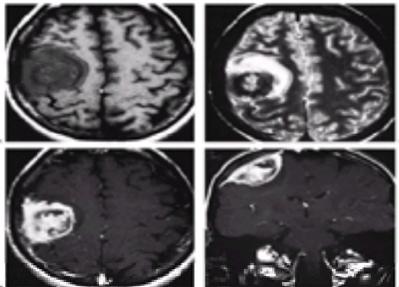

FIG. 54.2. Convexity meningioma. T1-weighted (A) and proton-density (B) axial MR images show a heterogeneous mass in the right parietal region. Surrounding edema is noted medial to the mass, and buckling of the cerebral white matter medially is also present. White matter buckling is considered a sign of extraaxial mass. T1-weighted axial (C) and coronal (D) MR images after gadolinium administration show marked enhancement within the lesion, with smaller nonenhancing areas correlating with known calcified portions. Coronal view shows dural enhancement and thickening both medially and laterally. The “dural tail” sign is most often seen with meningiomas but is occasionally seen with other tumors. (Courtesy of Dr. S. Chan, Columbia University College of Physicians and Surgeons, New York, NY.)

Posterior Fossa Meningiomas

Cerebellopontine angle meningiomas cause hearing loss and facial pain or numbness. Meningiomas are the second most common tumor of the posterior fossa after acoustic neuromas, and here they have a characteristic *en plaque* shape. Meningiomas recur more often than acoustic neuromas because they invade bone and cranial nerves; by the time that eighth nerve dysfunction is evident, the tumor is large. CT with bone windows demonstrates the infratemporal components, and MRI shows the intracranial tumor. Abnormalities on electronystagmogram, audiogram, and brainstem auditory evoked potentials testing are less common than with acoustic neuromas. *Clivus* meningiomas grow from the dura anterior to the brainstem (Fig. 54.3). Lateral extension into the petrous bone may complicate surgery because cranial nerves are affected. *Tentorial* meningiomas cause headache and cerebellar signs (Fig. 54.4). The major concern at surgery is the transverse sinus; if patent, it is not sacrificed. *Foramen magnum* meningiomas cause pain, gait difficulties, and hand muscle wasting. They are intimately entwined with the cranial nerves, making a complete resection difficult to achieve.

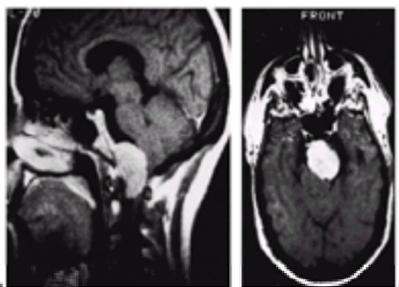

FIG. 54.3. Clivus meningioma. Contrast-enhanced sagittal (A) and axial (B) T1-weighted MR scans show a lower clivus–foramen magnum meningioma with marked compression of the medulla.

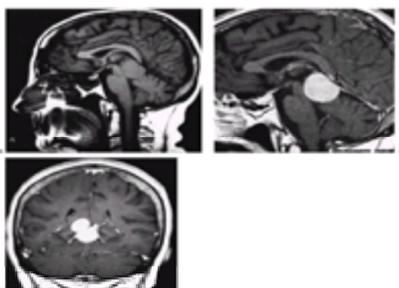

FIG. 54.4. Tentorial meningioma. A: T1-weighted sagittal MR image shows a large infratentorial mass that is isointense to brain and causing anterior displacement of the midbrain and inferior displacement of the superior vermis. T1-weighted sagittal (B) and coronal (C) MR scans after gadolinium administration demonstrate marked homogeneous enhancement of this mass, consistent with meningioma. The coronal view demonstrates the supratentorial component of the tumor. (Courtesy of Dr. S. Chan, Columbia University College of Physicians and Surgeons, New York, NY.)

Cavernous Sinus Meningiomas

Therapy for cavernous sinus meningiomas presents a challenge because resection may damage the cranial nerves. In young patients with no ocular muscle palsy, some recommend subtotal resection and radiotherapy. *Intraventricular* meningiomas arise from the arachnoid cells in the choroid plexus and account for 1% of all intracranial meningiomas. Surgical approaches include cortical or transcallosal incisions. The callosal approach is contraindicated in patients with a right homonymous hemianopsia because it may cause the syndrome of alexia without agraphia. *Sphenoid wing* meningiomas include the *en plaque* meningiomas

characterized by marked sphenoid hyperostosis, proptosis, visual loss, and third nerve palsy ([Fig. 54.5](#)). Surgery may include removal of the sphenoid wing itself. Some meningiomas here encase the middle cerebral artery.

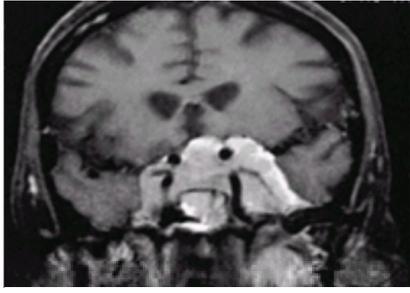

FIG. 54.5. Sphenoid ridge meningioma. Contrast-enhanced T1-weighted MR image shows an extensive sphenoid ridge meningioma with bilateral cavernous sinus invasion and encasement of both carotid arteries.

Spinal Meningiomas

Spinal meningiomas account for 25% to 46% of primary spinal cord tumors. Clinical signs and symptoms include radicular pain (72%), paraparesis (76%), tendon reflex changes (77%), and sphincter dysfunction (37%). Symptoms usually antedate the diagnosis by months or years. Paraparesis or paraplegia is seen in 80% of patients at the time of diagnosis, but most patients (67%) are still walking. Pathologically, the meningothelial and psammomatous tumors are most common. Complete removal is possible for most patients, but tumors anterior to the spinal cord and those with calcification may be difficult. After surgical resection, 82% of patients show improvement, 13% are stable, and 2% become worse. Postoperative mortality is low; pia mater invasion or adhesion to the surface of the cord increases the risk. Attention is paid to the radiculomedullary artery of Adamkiewicz, which feeds the anterior spinal system, generating a risk of paraplegia.

[Tumorigenesis And Genetic Conditions](#)
[Familial Conditions](#)
[Astrocytomas](#)
[Oligodendroglial Tumors](#)
[Ependymal Tumors](#)
[Neuronal Tumors And Mixed Neuronal Glial Tumors](#)
[Suggested Readings](#)

EPIDEMIOLOGY

Brain tumors are the third most common cause of cancer-related death in middle-aged men, and second to stroke in all neurologic causes of death. Most brain tumors affect people in the productive years of their lives. Gliomas are the most common primary brain tumor, accounting for 60% of all cases.

PATHOLOGY

Gliomas

Derived from the neuroglia, gliomas include astrocytomas, oligodendroglioma, ependymoma, and primitive neuroectodermal tumors. *Astrocytomas* are classified by histology. Grading systems are for prognosis and for selection of patients for therapeutic trials. Several systems have been proposed. In 1949, Kernohan advocated a classification that would parallel biologic behavior. Tumors were separated into low or high grade. Grades 1 and 2 were low-grade, while grades 3 and 4 were malignant gliomas. By the 1980s, a three-tiered grading was adopted by the World Health Organization, consisting of *astrocytomas*, *anaplastic astrocytomas*, and *glioblastoma multiforme*.

Limitations of Histologic Classifications

Brain tumor neuropathology is no longer a static discipline, and both clinicians and neuropathologists complement each other. Tissue sampling, particularly after a biopsy, may be limited, and undergrading may result. A typical case is that of a “low-grade” astrocytoma found in an older patient. Such a scenario needs to be viewed with suspicion, as it is exceedingly unusual to find low-grade astrocytomas in patients older than 45 years. Even after a large resection, the full extent of the tumor is not delineated, as neoplastic cells infiltrate normal brain. The presence of necrosis on a specimen could be erroneously attributed to a glioblastoma, but it is crucial to consider that *radiation necrosis* could be present. *Brainstem gliomas* offer a particular challenge, as tumor location may render surgery impossible, and a tumor may be treated without a histologic diagnosis ([Fig. 55.1](#)). In other instances, the seemingly benign histologic nature of a tumor contradicts a rapid clinical deterioration.

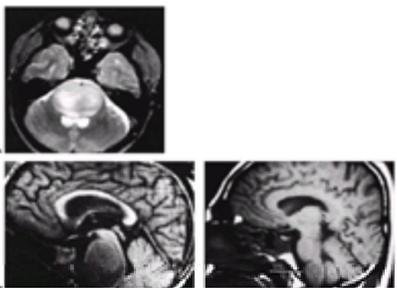

FIG. 55.1. Pontine glioma. Axial T2-weighted (A) and sagittal T1-weighted (B) MR images after gadolinium administration show massive enlargement of the pons by an intraaxial mass. There is no abnormal contrast enhancement. Pathology revealed a brainstem glioma. (Courtesy of Dr. S. Chan, Columbia University College of Physicians and Surgeons, New York, NY.) C: Brainstem glioma of medulla. T1-weighted MR scan in a patient with a subacutely progressing quadriplegia shows marked enlargement of the medulla (arrow). An exophytic component was biopsied and revealed low-grade astrocytoma.

Markers of Proliferation

Certain markers have been used to estimate the growth potential of astrocytic tumors; these include proliferating cell nuclear antigen (PCNA) and Ki-67 antigen. A labeling index (LI) can be determined by *in vitro* injection of bromodeoxyuridine, a thymidine analog, or ³H-thymidine into the tumor specimens followed by monoclonal antibodies against it. Improved progression-free survival has been associated with an LI less than 4%. In the future, genetic characteristics may be determinants of tumor behavior more than of histology itself.

TUMORIGENESIS AND GENETIC CONDITIONS

Several factors are implicated in tumorigenesis: activation of *protooncogenes*, loss of *tumor suppressor genes*, and stimulation by *growth factors*. The end result is a disruption of the cell cycle. Low-grade astrocytomas contain few, if any, cytogenetic aberrations; evolution to anaplastic astrocytoma and later to glioblastoma is accompanied by more genetic mutations. The earliest alterations involve loss of 17p, 13q, and chromosome 22. Transition from a low-grade glioma to an anaplastic astrocytoma is thought to be mediated by loss of 9p. Later progression to glioblastoma is preceded by deletion of 10q and amplification of the epidermal growth factor receptor (EGFR) gene. Accordingly, deletions of 9p and 17p are seen in all grades of gliomas, suggesting that these are early events. Abnormalities in chromosome 10 were observed in no patients with low-grade astrocytomas, 23% of patients with anaplastic astrocytoma, and 61% of those with glioblastoma multiforme. Tumor progression has been associated with an increase in the proportion of cells showing mutant p53. Based on chromosomal aberrations in gliomas, a model of malignant progression has been proposed. The *multistep theory* stipulates that multiple events are considered necessary for tumor development.

Oncogenes

Oncogenes are a counterpart to normal cellular genes, the protooncogenes. Oncogenes promote growth by encoding growth factors, growth factor receptors, and proteins affecting cell proliferation. Tumor development is considered to be a result of overexpression of oncogenes, well recognized in central nervous system (CNS) tumors as *c-erb-B1*, *c-myc*, and *ras*. The most recognized oncogene product is EGFR, which is encoded by the *c-erb-B1* protooncogene. Amplification of EGFR protooncogene was described in up to 50% of glioblastomas and 9% of astrocytomas. Other products are platelet-derived growth factor (PDGF) and PDGF receptor, as well as vascular endothelial growth factor (VEGF). Overactivation of one oncogene in itself may not be sufficient; multiple oncogenes may need to be activated, each one contributing to different aspects of cell growth. *Tumor suppressor genes* negatively regulate the activities of protooncogenes. Tumorigenesis results from activation of oncogenes and inactivation of tumor suppressor genes.

Retinoblastoma Gene

The first evidence of gene inactivation in tumor pathogenesis came from children with retinoblastoma, a childhood tumor. Retinoblastoma gene (*rb*) encodes a

105-kDa nuclear protein that may act as a tumor suppressor. Evidence for its role as a tumor suppressor comes from the fact that reintroduction of the normal *rb* gene into cultured retinoblastoma cells suppresses tumor growth. Retinoblastoma may be autosomal-dominant in inheritance, as well as sporadic. With autosomal-dominant disease, patients have bilateral retinoblastomas, osteosarcoma, or tumors of the pineal area (trilateral retinoblastoma). The disease has served as a model to explain how multiple genetic “hits” lead to tumorigenesis. About 5% of children with inherited retinoblastoma have a deletion at chromosome 13 in their normal cells; this is the first hit. Tumor development requires a second hit (a spontaneous mutation) in the other chromosome. The tumor cells then have loss of heterozygosity; that is, both alleles have lost the gene at 13q14. In the sporadic form of the disease, there are presumably two hits on the clones of retinal cells.

p53

Mutations at p53, the best characterized tumor suppressor gene, are the most common mutations in human cancers, commonly observed in colon and small cell lung carcinomas. Normal p53 gene and its gene product regulate cell proliferation by suppressing transition from cell phases G₁ to S and including apoptosis. Once the mutated p53 complexes with wild-type p53, it cannot exert its negative regulatory influence on cell growth. The gene is located at 17p13. p53 mutations are detected in 30% of gliomas (with earlier age at onset and longer survival), in 28% of glioblastomas and 36% of anaplastic astrocytomas; it is not detected in low-grade astrocytomas.

Role of Growth Factors

Many products of oncogenes resemble growth factors, and these regulate mitogenesis and gene transcription. Overexpression of a growth factor or its receptor may alter normal cellular proliferation. EGFR is found in 40% of gliomas; activation initiates cell cascades that lead to proliferation. The PDGF receptor has been localized to areas of proliferation, and it has been implicated in glioma development and transformation. *Insulin-like growth factor I* is increased in human gliomas. *Angiogenic growth factors* and *transforming growth factor* are overexpressed in malignant gliomas but minimally expressed in normal brain.

FAMILIAL CONDITIONS

Although most gliomas occur sporadically, about 15% of patients have a family history of cancer, further strengthening the genetic theories of tumor development.

Li-Fraumeni Syndrome

Patients with the Li-Fraumeni syndrome have breast carcinomas (24%), bone sarcomas (13%), brain tumors (12%), and soft tissue sarcomas (12%). Affected individuals inherit a germ-line mutation of p53 that results in a 25-fold increase in the likelihood of cancer. Reintroduction of normal p53 gene into cells that lack the gene inhibits tumor growth.

Neurofibromatosis Type 1

Von Recklinghausen neurofibromatosis is associated with CNS and peripheral tumors; most common are optic nerve gliomas, seen in 15% of affected individuals. Low-grade gliomas of the hypothalamus, hemispheres, or spinal cord are less common. Peripheral neurofibromas arise from cutaneous nerves, peripheral nerves, plexus, or spinal roots. The disease is autosomal-dominant in transmission, but 50% of patients have new mutations. The NF1 gene, a tumor suppressor gene, was cloned and localized at 17q11.2. Affected individuals have one mutated gene and one normal copy. Mutation of the normal gene (a second hit) is a prerequisite for tumor development. The abnormal gene product, *neurofibromin*, cannot downregulate p21-*ras*, the product of the *ras* protooncogene, which results in unrestrained proliferation and tumor formation.

Neurofibromatosis Type 2

Neurofibromatosis type 2 is dominantly inherited, with 95% penetrance. Cranial and spinal meningiomas, bilateral vestibular schwannomas, astrocytomas, and ependymomas may develop. Meningiomas tend to be multiple, and astrocytomas favor an intraspinal location. The gene locus for this tumor suppressor gene was identified at 22q12, and individuals with neurofibromatosis type 2 have a mutation at 22q11.2. If a second event occurs at the other 22q11.2 allele, the affected cell is liberated from the tumor-suppressive capabilities and tumors result. The NF2 gene encodes *merlin* (a moesin-ezrin-radixin-like protein), which is similar to proteins that regulate signals between the cell cytoskeleton and the cell membrane.

Von Hippel-Landau Disease

Von Hippel-Landau disease may manifest with multiple hemangioblastomas along the neuraxis (cerebellum, brainstem, spinal cord) and retina, renal cysts, and renal cell carcinomas. A mutation at chromosome 3p has been described.

Familial Polyposis Syndromes

The familial polyposis syndromes associated with brain tumors may have a mutation of the tumor suppressor gene at the locus for adenomatous polyposis coli, 5q21. In Turcot syndrome, adenomatous polyposis coli is associated with neuroepithelial CNS tumors, including astrocytomas, glioblastoma, and medulloblastoma. There are two distinct genetic alterations. One involves a germ-line mutation in the adenomatous polyposis coli gene, probably a tumor suppressor gene. The other is a germ-line defect in a gene responsible for deoxyribonucleic acid (DNA) nucleotide mismatch repair. Patients with hereditary colon cancer and neurologic symptoms are suspect. Likewise, patients diagnosed with a CNS tumor and having a family history of adenomatous polyposis coli should undergo surveillance colonoscopy. *Gardner syndrome* is characterized by osteomas and soft tissue tumors. The two syndromes may occur in the same patient. Patients with familial polyposis should be examined for manifestations of Gardner syndrome. Likewise, if Gardner syndrome is suspected, brain computed tomography (CT) is recommended.

Multiple Endocrine Neoplasia

Multiple endocrine neoplasia (MEN) type 1 syndrome includes pituitary tumors, pancreas islet cell neoplasms, and parathyroid adenomas. An abnormality is described at 11q. In MEN type 2, patients have medullary thyroid carcinoma and pheochromocytoma. The abnormality maps to chromosome 10.

ASTROCYTOMAS

General

Astrocytomas constitute 25% of all brain tumors. The annual incidence of low-grade astrocytomas is about 0.9 per 100,000 population. Median age at diagnosis is 35 years, much younger than for malignant gliomas. There is a slight male predominance. The annual incidence of glioblastoma multiforme is 4.5 per 100,000 population, representing about 28% of all brain tumors in the United States; the incidence of anaplastic astrocytomas is 1.7 per 100,000, about 27% of all brain tumors. The probability that an astrocytoma is histologically malignant is 34% at ages of 3 to 34 years, and rises to 85% after age 60 years. Before age 25, 67% of astrocytomas are found in the posterior fossa; after age 25, 90% are supratentorial.

Pathology

Grossly, low-grade astrocytomas are superficial soft, gray expansions of cortex, with adjacent white matter involvement; borders are indistinct. Glioblastomas display a multiplicity of colors, textures, and consistencies. The surrounding white matter is edematous. Location is usually in the white matter, most commonly frontal (31%), temporal (32%), and frontoparietal (11%). Tumors may encompass different lobes. Spinal cord, brainstem, or cerebellar locations are rare. Ten percent of glioblastomas develop in the gray–white matter junction and may be confused with metastases.

Histopathology varies, depending on subtype. Low-grade astrocytomas show evenly distributed neoplastic cells; cytoplasm is abundant, and microcystic changes are characteristic. Mitosis is rare, and the nuclei are uniform. The infiltrated brain appears well preserved. *Protoplasmic* astrocytomas are aggressive and can transform into secondary glioblastoma. *Fibrillary* astrocytomas have a limited proliferative capacity; this category includes the pilocytic astrocytoma. *Gemistocytic* tumors have the worst prognosis. Before a tumor is determined to be “low-grade,” all available tissue should be carefully examined. Foci of anaplasia have been observed in up to

50% of patients with “low-grade” astrocytomas at diagnosis. *Anaplastic* astrocytomas and glioblastoma are composed of cells with small, dark nuclei that vary in size and shape. Cytoplasm is scant, mitotic figures are present, and there is pseudopalisading (tumor cells arranged in picket-fence formation around a central area of necrosis). Endothelial hyperplasia is seen, but only glioblastomas have necrosis. There is variety of cell morphology and architecture, hence the name multiforme. Glial fibrillary acidic protein staining is seen in the cytoplasm of astrocytes and astrocytic tumors, but it is absent in highly undifferentiated tumors. *Giant cell glioblastoma* favors the temporal lobe; patients have a better prognosis. *Gliosarcomas* comprise both glial and sarcomatous elements.

Clinical Manifestations

Patients with low-grade astrocytomas may have years of seizures with nondiagnostic studies. Most typically for malignant gliomas, patients present with several months of progressive neurologic deficits; about 10% have symptoms for longer than 1 year. Memory and personality changes may be unnoticed until an ictal event leads to seeking medical attention.

Imaging

Typically, *low-grade astrocytomas* are nonenhancing lesions on magnetic resonance imaging (MRI), appearing hypointense to surrounding brain on T1-weighted imaging and usually homogeneous and well circumscribed. It may be difficult to distinguish tumor from edema, and there may be mass effect. Enhancement is faint, if present at all. *Anaplastic astrocytomas* and *glioblastoma* appear as contrast-enhancing, ring-shaped, white matter lesions on MRI and CT. Absence of enhancement should not exclude the diagnosis of a malignant astrocytoma, but once enhancement is observed, a low-grade histology should be doubted and may be due to sampling. There is surrounding edema, best appreciated on T2-weighted images, but less than with metastases. In contrast to metastases, fewer than 3% of malignant gliomas are multicentric. The central area of nonenhancement represents necrosis; enhancement reflects tumor and neovascularization. *Positron-emission tomography* shows hypermetabolic areas associated with malignant change.

Treatment

Defining Treatment Results

In the evaluation of new agents or comparison of their results to standard clinical treatments, there are three main measures: *response*, *time to progression*, and *survival*. *Response* is determined radiographically and clinically after two cycles of chemotherapy or after radiation. Measurements are taken along the largest diameter of the contrast-enhancing portions of the lesion, and then along the dimension perpendicular to it; these are then multiplied to obtain the cross-sectional area. *Complete response* means disappearance of all enhancing areas of tumor on MRI or CT, along with a stable or improving examination. *Partial response* is defined by a greater than 50% decrease in tumor size, with a stable or improving examination. A *minor response* corresponds to a 25% to 50% decrease in tumor size, *stable disease* to less than 25% change in tumor size, and *progressive disease* to tumor enlargement greater than 25%.

Specific problems in response evaluation include the following:

1. The tumor may enlarge along a third dimension that is not part of the conventional tumor measurement.
2. The dose of steroids at the time of MRI may affect the degree of enhancement, artificially altering tumor size; it is then preferable to have the patient on a stable dose of steroids when comparing studies.
3. Concurrent medications, such as anticonvulsants, affect performance and confound clinical response evaluation.
4. The standard response criteria apply to tumors that enhance, and there are no criteria for evaluating response for cystic or nonenhancing lesions.

Furthermore, response does not take into consideration changes observed in the periphery, which is known to be diffusely infiltrated by neoplastic cells. Recent studies have put into question the validity of response criteria as indicators of treatment benefit, and have found a lack of correlation between radiographic response and overall survival. Two other factors may be more clinically important: *time to progression*, defined as the time from treatment onset to radiographic progression of the tumor; and *survival*, the time from the onset of treatment to death.

From 13% to 45% of patients with gliomas return to work in the postoperative or postirradiation periods; up to 70% have a satisfactory level of functioning during an average of 8 months. Functional decompensation occurs late in the course of the disease and precedes terminal deterioration. This short window of opportunity is crucial in planning treatment.

Surgery

Surgery is controversial for low-grade astrocytomas. As imaging has become more sophisticated, tumors are being detected earlier, when the patient is neurologically intact. It is not clear whether earlier rather than delayed surgery will increase survival. Many delay surgery until there is progression. On the other hand, surgery provides tissue for histologic diagnosis, as MRI may not always predict grade. Absence of enhancement, typical of low-grade astrocytomas, is seen in up to 30% of patients with anaplastic astrocytomas and 4% of those with glioblastoma. The extent of surgery is also not agreed on. The goal is to remove as much tumor as possible without compromising function. Low-grade astrocytomas infiltrate the surrounding brain, and it is difficult to discern tissue planes; furthermore, invasion of functional cortex by tumor may limit a safe resection ([Fig. 55.2](#)).

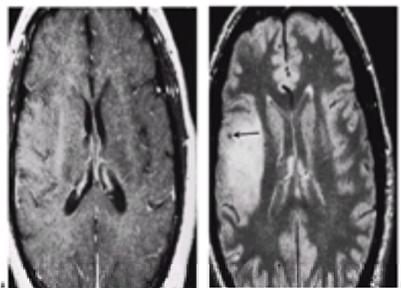

FIG. 55.2. Low-grade infiltrative astrocytoma. Contrast-enhanced T1-weighted (A) and T2-weighted (B) MR images show a right temporal low-grade infiltrative astrocytoma. There is faint contrast enhancement. The site of the stereotactic biopsy is visible (arrow). The lesion is unchanged for 3 years without treatment.

For malignant gliomas, radical removal offers a survival advantage, compared to biopsy. *Surgery* can achieve several objectives: (1) alteration of cell kinetics, inducing entry of inactive cells into division and thus making them more susceptible to radiation and chemotherapy; (2) reduction of tumor burden and disturbance of the blood–brain barrier (BBB), potentiating the effect of chemotherapy; and (3) decreased intracranial hypertension and improvement in function. *Stereotactic biopsy* should be reserved for (1) poorly defined lesions in deep or inaccessible locations in patients who are neurologically intact and (2) patients too ill for large resections. Stereotactic biopsy has a less than 3% mortality, a less than 1% morbidity, and about a 3% incidence of hemorrhage. Open craniotomy can also benefit from image-directed stereotactic techniques.

Radiation Therapy

For low-grade astrocytomas, the benefit of adjuvant radiation is controversial. Most studies are retrospective, and they are not uniform with respect to patient selection, type of surgery, location, or radiation dosage. Although randomized trials have not been completed, there is a suggestion that radiation is effective. In 1975, Leibel and colleagues studied 147 patients with low-grade astrocytomas, excluding those who had a complete surgical resection. Radiation offered a distinct survival advantage; 5- and 10-year survivals of 46% and 35% for those who received radiation, compared to 19% and 10% for those who did not.

For anaplastic astrocytomas and glioblastomas, radiation remains the most effective treatment, as demonstrated by numerous trials. The value of postoperative radiation was most definitely shown in a cooperative trial (Walker, 1978). Median survival for patients undergoing surgery alone was 17 weeks compared with 37.5 weeks for those treated with radiation postoperatively ($p = 0.001$). Radiation causes DNA breaks, and damage depends on the presence of oxygen. Brain tumors have a lower oxygen tension than the surrounding normal cortex, which helps explain their relative radioresistance. Survival correlates well with total dose of radiation; beyond 70-Gy, the benefits of treatment are outweighed by the toxic effects on the surrounding brain. Tumor growth during or immediately after irradiation or inability to decrease the steroid dose is an ominous sign. Because most recurrences are local, radiation is given to the tumor bed and 2 cm of surrounding brain, not to the whole brain (Fig. 55.3). Radiation is administered daily five times a week for 6 weeks, for a total dose of 6,000 cGy.

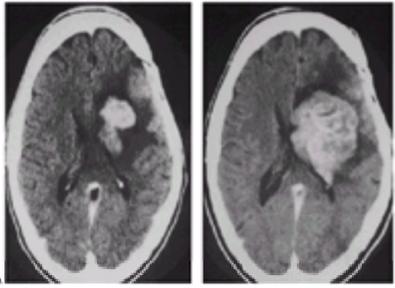

FIG. 55.3. Glioblastoma. **A,B:** Contrast-enhanced CT in a patient with an extremely rapidly recurring left frontotemporal glioblastoma shows a dramatic increase in tumor size in the intervening 8 weeks between the two scans.

Chemotherapy

The introduction of the nitrosoureas has been the most important development in brain tumor chemotherapy. The 40% response rate to carmustine (BiCNU) for recurrent gliomas has not been surpassed to date. The limitations of chemotherapy stem from several factors, including inherent drug resistance and lack of penetration across the BBB. Some responses have been reported in low-grade astrocytomas after chemotherapy. For anaplastic astrocytomas and glioblastomas, median survival is not much improved when carmustine is given in addition to surgery and radiation (10 months), compared with survival after surgery and radiation alone (9.25 months). Further analysis showed that the only long-term survivors were in the carmustine arm. Tumor cells from patients younger than 40 years are more sensitive to carmustine than those of older patients. Carmustine is lipophilic and rapidly enters the cerebral circulation. The usual dose is 80 to 100 mg/m² per day for 3 days every 6 to 8 weeks, as allowed by blood cell recovery. Carmustine toxicity, particularly pulmonary, is cumulative and is seen at total doses greater than 1.2 g/m². Procarbazine hydrochloride (Matulane) may be used at a dose of 150 mg/m² per day for 28 days followed by a 28-day rest.

Novel Therapies

Exciting new areas of research for gliomas include restoration of lost tumor suppressor gene function, induced alterations in the cell cycle, inhibition of metastasis-inducing metalloproteinases, inhibition of angiogenesis, and inhibition of signal transduction pathways. The other major area of research relevant to experimental therapeutics for gliomas is the abrogation of the BBB. These are discussed below.

Novel Molecular/Biochemical Therapies

Gene Therapy. A gene encoding for a protein to which the host is deficient can be introduced via a viral vector and inhibit the expression of an abnormally expressed protein. In gliomas, gene therapy has centered on herpes simplex–thymidine kinase (HSTK) gene. Glioma cells transfected with HSTK gene produce thymidine kinase and are targets for antiviral therapy with ganciclovir sodium (Cytovene). When exposed to ganciclovir, they accumulate phosphorylated ganciclovir, a toxic metabolite. There is a bystander effect, whereby neighboring cells not transfected also die. Clinical trials are in progress; one study reported regression in small lesions in 5 of 15 patients. p53 gene therapy is based on the finding that p53 is mutated or deleted in one-third of gliomas; tumor cells with wild-type p53 are more generally sensitive to chemotherapy and radiation. Glioma cells transfected *in vitro* with an adenovirus containing wild-type p53 undergo apoptosis or cell cycle arrest. *In vivo* experiments await the development of better viral vectors to increase transfection rates.

Alterations in Cell Cycle. Activity changes in cyclin and cyclin-dependent kinases (CDKs) can alter the cell cycle. Studies using CDK modulators such as flavopiridol, PDGF, or fibroblast growth factor are in progress. Metastasis-inhibitors include matrix metalloproteinase inhibitors, which block the effects of enzymes associated with metastasis. Antiangiogenesis therapies include antibodies to VEGF, thalidomide, and TNP-470. In the area of inhibition of signal transduction, studies have targeted protein kinase C (PKC) because of its importance for signal transduction and because of high concentrations in gliomas. PKC inhibitors such as UCN-01, tamoxifen citrate (Nolvadex), and bryostatins are in early clinical testing.

Alteration of the BBB. P-glycoprotein is partially responsible for the intact BBB, which acts like an efflux pump for natural-product drugs. High-dose tamoxifen inhibits P-glycoprotein efflux of natural-product chemotherapy drugs out of the cell. One preliminary study showed that pretreatment with tamoxifen in animals led to a threefold increase of intratumoral concentrations of paclitaxel (Taxol), an effective antiglioma agent *in vitro* (Fine, Bruce). These investigations may lead to the use of other anticancer agents typically not useful in the past because of the BBB (Fine, Balmaceda, and Bruce). New agents that by design are more lipophilic and may cross the BBB include temozolomide and topotecan hydrochloride (Hycamtin). Biodegradable polymers have attempted to bypass the BBB. These are impregnated with chemotherapy and surgically placed in the tumor bed. Chemotherapy is slowly released into the surrounding tissue. Studies with carmustine-impregnated polymers have shown a small but real survival benefit (31 weeks versus 23 weeks for patients with recurrent gliomas treated with carmustine wafers versus placebo wafers after surgery, respectively). This approach depends on passive diffusion of carmustine, usually less than 5 mm. Attempts to increase diffusion into the peritumoral region, the most common site for glioma relapse, have exciting but preliminary results. Studies by Bruce and Fine at Columbia in rodents have demonstrated cures in glioma implanted into rat brains when topotecan (a topo I inhibitor) was infused by high-flow interstitial microinfusion. Excellent drug penetration into distal areas of the brain was observed without toxicity. Brain tumors preferentially express Topo I in contrast to normal brain.

Neoadjuvant Chemotherapy. Preirradiation chemotherapy allows new agents to be studied in their true neoadjuvant setting, prior to development of resistance. Several studies have concluded that irradiation can be safely delayed by several cycles of chemotherapy without compromising outcome in gliomas.

High-dose Chemotherapy. Brain tumors are attractive to consider for high-dose chemotherapy. They may be sensitive to melphalan (Alkeran), thiotepa (Thioplex), or nitrosoureas, all of which have myelosuppression as their main toxicity. Drugs effective against brain tumors have dose–response relationships. Higher doses may better penetrate the BBB. Patients most likely to benefit are those with “responsive” tumors (oligodendrogliomas and primary CNS lymphoma) and minimal disease at treatment.

Novel Radiation Therapies

Short-course Radiotherapy. This type of radiotherapy uses larger-than-conventional fractions over a shorter period of time (e.g., 37 Gy over 3 weeks instead of 60 Gy over 6 weeks). Studies suggest that for poor-prognosis patients this treatment may be a reasonable option, as it is easier to tolerate, and could offer patients more time off treatment, without compromising overall survival.

Brachytherapy. Local implantation of radioactive seeds (iodine 125 or iridium 192) into the tumor bed allows delivery of radiation directly into the tumor while sparing the normal brain. Continuous low-dose radiation over several days allows neoplastic cells to reoxygenate and enter active cell division, making them more sensitive to treatment, especially when they are in G₂ phase. Brachytherapy requires surgical intervention, and there are limitations on size, geometry, and tumor location. Only about 20% of patients are eligible. Treatment is well tolerated, but radionecrosis requiring reoperation develops in 20% to 40% of patients. Improved survival for

recurrent glioblastomas has been reported, but there is no clear advantage for anaplastic astrocytomas.

Superfractionation. This approach consists of daily, multiple, low-dose fractions of radiation (e.g., three doses per day, total 5,000 cGy). In theory, the higher total dose will result in increased oxygenation, which lowers resistance to radiation. Furthermore, because of the increased number of fractions, the normal brain is relatively protected. Studies are not yet conclusive.

Radiation Sensitizers. Metronidazole and misonidazole interfere with molecular repair mechanisms and sensitize hypoxic cells to the effects of radiation. Trials have failed to demonstrate an improved survival over radiation alone.

Boron Neutron Capture Therapy. This form of therapy uses thermal neutrons generated by reactors. Neutron isotopes of boron 10 capture a neutron to become boron 11, which can dissipate energy in a localized fashion. Pathologic studies showed complete eradication of tumor in some patients.

Stereotactic Radiosurgery. Delivery of a large single dose of radiation to a small target permits an increase in total dose at sites of greatest tumor cell density while sparing normal brain. Photon beams from both gamma-knife units and linear accelerators can be used. A national trial is studying the role of stereotactic radiosurgery (SRS) in newly diagnosed malignant gliomas. After surgery, patients are randomized to receive either SRS followed by conventional radiation and carmustine or conventional radiation and carmustine. Results are not yet available. Acute complications related to edema are transient in most patients. The best candidates are patients with small (less than 3 cm in diameter), radiographically distinct, and focally recurrent glioblastomas. Larger lesions and those adjacent to eloquent cortex must be evaluated with caution. There is a survival advantage with SRS for some patients, especially if it is appropriately used with surgery and other adjuvant therapies. Actuarial risk of reoperation can be as high as 48% and increases with larger target size.

Hyperthermia. This technique induces apoptosis in poorly oxygenated, poorly vascularized, noncycling cells (i.e., cells resistant to radiation). The combination of hyperthermia with radiation is being explored.

Supportive Treatment

Increased intracranial pressure from edema may develop. Corticosteroids are the most effective agents for symptom relief. Side effects include truncal obesity, diabetes, psychosis, insomnia, excessive appetite, and stress fractures. Patients are usually placed on corticosteroids during radiation. The lowest possible dose is attempted. Failure to taper the steroid dose is an indication that the tumor may be progressing. The rate of tapering depends on the duration of treatment. In the terminal stages of disease, steroids may be increased to as high as 40 to 80 mg per day as a comfort measure.

Overall Goals of Therapy

For patients with *low-grade* tumors, the benefit of treatment, compared to the neuropsychologic and cognitive impact of treatment itself, needs to be delicately balanced. For patients with *chemosensitive* tumors, treatment strategies may delay or attempt to avoid radiation altogether. If the tumor responds to chemotherapy, a smaller radiation field may minimize side effects without compromising outcome. One needs to consider potential long-term sequelae of chemotherapy (sterility, secondary malignancies) and compare them to potential toxicities of radiation and the behavior of the tumor itself. Above all, an attempt should be made to preserve a patient's *quality of life*. As gliomas usually affect middle-aged, productive individuals, supportive treatment also implies addressing the psychologic consequences of loss of control, alteration in family dynamics, and change in their roles as professionals or parents. Attention should be also provided to the *caregivers*, often forgotten players in the course of the disease.

Clinical Course

The frequency of dedifferentiation of low-grade astrocytomas is a matter of debate, but in about 50% of cases, there is a change to a more malignant form. More than 90% of recurrences occur within 2 cm of the original tumor. This observation supports the use of focal modalities of therapy, such as SRS. Conversely, a common pattern of spread is along white matter tracts, particularly the corpus callosum; and lesions distant from the original tumor site develop in 5% to 10% of patients. The observation of both the focal and infiltrative nature of tumor growth plays a key role in ultimately guiding therapy. Subependymal spread is rare but may be seen in young patients after intensive therapy. Cerebrospinal fluid (CSF) seeding develops in fewer than 2% of patients, who experience lumbosacral pain and leg weakness, and usually occurs late in the course of the disease (mean, 14.1 months after diagnosis, suggesting that most patients do not live long enough for this condition to develop). Extraneural metastases are seen in fewer than 0.5% of patients; gliosarcoma is most likely to cause such spread. Local dissemination to scalp or bone may be seen after multiple surgeries. Patients usually expire from local compression or microscopic invasion of vital areas.

Management of Recurrent Disease

Some advocate surgery at progression. If histology is "low-grade," then observation is recommended. If the histology shows anaplasia, then the patient should be treated for a more aggressive tumor. Others consider a tumor aggressive once it has progressed clinically or radiographically, and recommend treatment independent of histology at the time of recurrence. When possible, biopsy should be targeted to areas of enhancement.

Prognosis

For low-grade astrocytomas, 5-year survival is 40% to 65%; 10-year survival is about 20% to 40%. Median survival for patients with glioblastoma after surgery and radiation is 37 weeks, and less for patients older than 60 years. Over the last 20 years, the number of long-term survivors has increased without any significant change in overall survival. About 20% live more than 3 years after diagnosis. *Age* is the single most important determinant of prognosis; tumors in patients younger than 10 or older than 45 years fare worse. Tumor grade (anaplastic astrocytoma), good preoperative performance status, a complete surgical resection, and radiation greater than 6,000 cGy are prognosticators of better survival. *Histologic features* such as necrosis indicate a short survival. *Gene alterations*, such as p53 mutations or loss of heterozygosity on chromosomes 10 and 17, have been correlated with progression from astrocytoma to glioblastoma.

Astrocytic Variants

Pilocytic astrocytomas are the most common astrocytic variant. Peak incidence is in the second decade. The term is synonymous for what was called "juvenile pilocytic astrocytoma." The typical location is midline: cerebellum, third ventricle, or brainstem. Compared to diffusely infiltrating astrocytomas, pilocytic variants tend to be circumscribed and have a better prognosis. Microscopically, one sees bipolar cells with thin, hairlike processes, hence the term *pilocytic*. Macroscopically, they appear well circumscribed and have a cystic structure associated with a mural nodule. Histologic malignancy is rare. Behavior is indolent, and surgery offers the best outcome. Ten-year survival is 70%.

Pleomorphic xanthoastrocytomas are rare and occur in young adults. In up to 78% of cases, it is associated with seizures. Leptomeningeal infiltration is common, but the dura is spared. MRI shows a superficially located, cystic lesion with a mural nodule. Histologically, there is cellular pleomorphism; mitosis are rare. There are abundant lipid accumulations, hence the term *xantho* (yellow in Greek). Xanthoastrocytomas have a stronger potential for aggressive behavior than other circumscribed astrocytomas.

Subependymal giant cell astrocytoma occurs in the first two decades of life. The tumor is well demarcated, and calcifications are common. Favorite locations are the lateral ventricles and caudate nucleus. Five percent of patients with tuberous sclerosis have a subependymal giant cell astrocytoma arising in the foramen of Monro during adolescence. The tumors are slow-growing; surgical resection offers the best long-term outcome. Some advocate periodic MRI for patients with tuberous sclerosis. With surgery, 10-year survival is 80%.

Desmoplastic astrocytomas of infancy is seen exclusively in infants. Tumors are very large and superficially located in the frontal lobe, and tend to thin the overlying calvarium. Prognosis after surgery is good despite the large size and histologic pleomorphism.

Gliofibromas occur through the neuraxis. Median age at diagnosis is 7 years. Histologically, one finds neoplastic astrocytes and a second population of cells, possibly fibroblasts. Only 14 cases have been reported. The tumors can progress.

Unusual Growth Patterns

Gliomatosis cerebri is characterized by diffuse infiltration of neoplastic astrocytes throughout a large portion of a hemisphere. Histologically, the tumor resembles a diffuse astrocytoma, but anaplastic foci may be found. T2-weighted MRI shows extensive areas of hyperintensity (Fig. 55.4 and Fig. 55.5). Contrast enhancement is usually absent, but it may be seen at a later stage of the disease. Clinical course varies from slowly to rapidly progressive. Radiotherapy appears to stabilize or improve neurologic function in some patients.

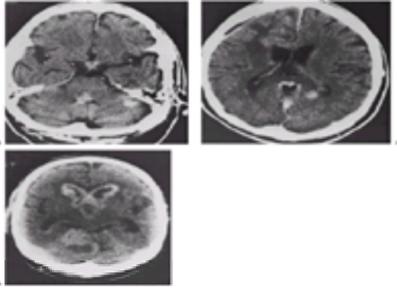

FIG. 55.4. Glioblastoma, ependymal and meningeal seeding (leptomeningeal gliomatosis). **A:** Axial contrast-enhanced CT demonstrates abnormal enhancement in the suprasellar cistern along the left tentorium and subependymal region of the fourth ventricle owing to CSF seeding of tumor. **B:** Higher scan section from the same examination demonstrates persistent abnormal enhancement and mild mass effect at the primary site (right frontal), where a chronic postoperative extraaxial collection is also seen. Abnormal enhancement in the periatrinal regions, especially on the left, indicates further subependymal seeding. **C:** In another patient with a cerebellar glioblastoma, contrast enhancement outlining the frontal horns and the right tentorium indicates leptomeningeal gliomatosis.

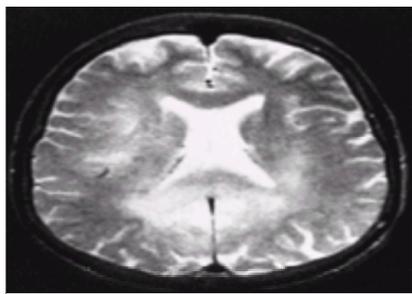

FIG. 55.5. Gliomatosis cerebri. T2-weighted MR scan shows widespread areas of increased signal in both cerebral hemispheres. Stereotactic biopsy revealed anaplastic astrocytoma.

Leptomeningeal gliomatosis can be seen in up to 25% of patients at autopsy; higher rates are seen in children. Symptoms include radiculopathy, myelopathy, or cranial nerve findings. CSF protein may be elevated.

OLIGODENDROGLIAL TUMORS

General

Oligodendrogliomas stand apart from other CNS malignancies. First, they are more indolent in behavior. Furthermore, they are exquisitely chemosensitive in contrast to other glial neoplasms. This recognition may allow neurooncologists to develop treatment strategies that may eventually be applicable to other types of brain tumors.

Epidemiology

Oligodendrogliomas account for about 5% of all primary brain tumors and 30% of intracranial gliomas. Median age at diagnosis is 50 years; some studies suggest a male predominance. The tumors are exceedingly rare in children.

Clinical Manifestations

Because oligodendrogliomas are commonly cortical or subcortical, seizures are the initial presentation in up to 75% of patients. Seizures are usually present for a median of 15 months but may be present for years (rarely, up to 10 to 20 years) before tumor diagnosis. The frontal lobe is the most common location, followed by the temporal and parietal lobes. About 25% of tumors cross the midline to the opposite hemisphere; posterior fossa or spinal cord location is unusual. Leptomeningeal dissemination is rare at presentation. On examination, tumors are remarkably silent despite their large size. This may be due to their slow-growing, infiltrative nature.

Pathology

Grossly, one observes calcification, cystic degeneration, necrosis, or hemorrhage. Tumor arises from a subcortical location and infiltrates the cortex. *Histologically*, tumor cells are homogeneous and have a characteristic “fried egg” appearance, showing a clear perinuclear halo surrounding a dense central nucleus as a result of a fixation artifact. This typical appearance is less common in anaplastic oligodendrogliomas. The neoplastic cells may be distributed into lobules separated by branching vessels, forming a “chicken wire” pattern. Microcyst formation from mucinous accumulation is common.

Histologically, oligodendrogliomas are tumors without anaplastic features. *Anaplastic* oligodendrogliomas have features of anaplasia: mitosis, endothelial proliferation, mitotic activity, and necrosis. Necrosis should not cause confusion with glioblastoma multiforme. *Mixed oligoastrocytomas* are composed of both oligodendroglial cells and astrocytes, which are believed to arise from a common precursor, the oligodendrocyte-type 2 astrocyte. The exact proportion of astrocytic cells required to classify a tumor as mixed is a matter of debate; some require the minor component to be least 30% of the overall cell population. An astrocytic component has been associated with a worse prognosis. Growth may vary from that of a solid tumor that destroys the parenchyma to isolated tumor cells that infiltrate normal brain. The parenchyma-destructive pattern is more commonly associated with contrast enhancement, neurologic deficits, and more aggressive behavior.

There is no specific marker for oligodendroglial differentiation. The limitations of current histopathologic measures become apparent in the assessment of “progressive” oligodendrogliomas. By definition, these tumors lead to worsening symptoms and sometimes death. Despite their aggressive behavior, a second operation may reveal low-grade pathologic features identical to those of the original tumor. Researchers are turning to molecular genetics to explain and predict behavior. Allelic loss at chromosomes 1p and 19q have been implicated in oligodendroglioma development, and it has been postulated that 19q may contain a tumor suppressor gene. Anaplastic oligodendrogliomas may have further allelic losses on 9p and 10. Genetic changes in some oligodendrogliomas are being studied as markers of chemosensitivity.

Imaging

Certain features are suggestive of, but not specific for, oligodendrogliomas. On CT, the tumor is hypodense, well demarcated, and occasionally cystic. Calcification is common; intratumoral hemorrhage may be seen. On T1-weighted MR images, the tumor is hypo- to isointense and appears to infiltrate adjacent brain with no surrounding edema. With contrast, most "low-grade" oligodendrogliomas do not enhance; those that do are usually anaplastic oligodendrogliomas or "low-grade" oligodendrogliomas that have progressed.

Treatment

As oligodendrogliomas vary greatly in their behavior, treatment must be tailored to the specifics of the patient's tumor. For a patient with a "low-grade" oligodendroglioma and controlled symptoms, the best approach may be observation. A patient with a similar histology at diagnosis whose tumor has shown growth should be treated, usually with surgery, radiation, and/or chemotherapy. Newly diagnosed anaplastic oligodendrogliomas should receive therapy after surgery. Most authors recommend prophylactic use of anticonvulsants. This stands in contrast to practice in the treatment of other types of brain tumors, where use of anticonvulsants is debatable. Tumor resection and radiotherapy may facilitate seizure control.

Surgery

The extent of surgery varies with location, signs, symptoms, and proximity to eloquent areas. Biopsy is preferable for infiltrative lesions in an eloquent area that cause no mass effect, or for patients who have a normal examination. Resection is indicated if there is mass effect, the patient has progressive symptoms, and the tumor is not close to critical areas. Surgery with electroencephalograph monitoring may serve for both tissue diagnosis and seizure control.

Radiation Therapy

At most institutions, radiation is given to patients with anaplastic oligodendrogliomas at diagnosis, independent of the extent of surgery, or to patients with low-grade oligodendrogliomas at diagnosis whose tumors have mass effect or progress. The role of radiation in the treatment of low-grade, nonprogressive oligodendrogliomas is controversial. Infiltrative tumors may involve several lobes concurrently, and patients with such lesions, although seemingly normal, may have significant neuropsychologic deficits. Conversely, the main concern with administering radiation is the possible deterioration of neuropsychologic function when large areas of the brain are irradiated. Good local control is usually obtained with 60 Gy.

Chemotherapy

The realization that oligodendrogliomas are extremely chemosensitive has spurred new interest in the treatment of these tumors. As focal therapy becomes more effective, late relapses may involve the leptomeninges or distant organs, making the role of chemotherapy much more vital. In 1988, Cairncross and Macdonald found that oligodendrogliomas, unlike other glial tumors, had excellent response rates (75% to 100%) to the combination of procarbazine, CCNU, and vincristine (PCV). At recurrence, 100% of PCV-naive patients may respond to PCV (Fig. 55.6). Many institutions administer chemotherapy, in addition to radiation, to anaplastic oligodendrogliomas at diagnosis or to tumors for which radiation has failed. Response may be better for contrast-enhancing than for nonenhancing masses. There are many unanswered questions:

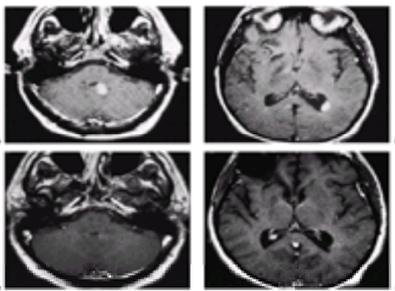

FIG. 55.6. Disseminated oligodendroglioma. Contrast-enhanced MRI in a patient with recurrent anaplastic oligodendroglioma shows ependymal seeding of the left lateral (A) and fourth (B) ventricles. C,D: In the same patient 4 months later, there is complete response of both intraventricular lesions after two cycles of PCV chemotherapy.

1. The benefit of chemotherapy for newly diagnosed low-grade oligodendrogliomas is not clear. One study showed responses to PCV in seven of seven patients; the responses were sustained without radiotherapy for a median of 35 months.
2. The role of PCV as adjuvant treatment for newly diagnosed anaplastic oligodendrogliomas, in addition to radiation, is not known; and this is the basis for an ongoing multicenter trial.
3. It is uncertain whether mixed oligoastrocytomas are as sensitive to PCV as pure oligodendrogliomas. The difference may be due to the genetic constitution of the tumor; that is, some tumors may be more of an "oligodendroglioma" genotype with genetic losses at 1p and 19q, while other, less chemosensitive tumors may have more "astrocytic" features, such as p53 mutation.
4. It is not known whether PCV given as sole treatment can avoid radiation therapy. The PCV regimen is not curative, and the tumor recurs in all patients. Furthermore, PCV may cause prolonged myelosuppression, which may limit the use of chemotherapy in the future.

The biochemical basis for this exquisite *chemosensitivity* is unknown. The tumors are sensitive to carmustine and procarbazine hydrochloride (Matulane), both of which alkylate DNA at O6-guanine. Repair is mediated by the DNA-repair enzyme O6-methylguanine methyl transferase (MGMT). Sensitivity appears dependent on the level of MGMT in tumor cells. MGMT-positive cells become resistant to nitrosoureas, whereas depleted cells are sensitive. Low levels of MGMT have been found in both rat oligodendrocytes and PCV-responsive human oligodendrogliomas.

Prognosis

The limitations of standard measures as prognosticators of tumor behavior are well known. Age, extent of resection, performance status, and labeling indexes have been statistically associated with survival. Median survival for low-grade oligodendrogliomas after subtotal resection alone is reported at 2 years, and that after complete resection and radiotherapy at 7.9 years. Shaw (1995) reported a median survival and 5- and 10-year survival rates of 4.3 years, 45%, and 23% for anaplastic oligoastrocytomas versus 4.6 years, 46%, and 26% for anaplastic oligodendrogliomas, respectively. Disease recurrence beyond 5 years is common, so patients need frequent monitoring. The excellent survival for some patients with low-grade oligodendrogliomas without radiation or chemotherapy obliges clinicians to put in perspective any treatment strategy designed for this subgroup of patients.

EPENDYMAL TUMORS

These tumors arise from ependymal cells that line the ventricles or the central canal of the spinal cord. The median age at diagnosis is between 3 and 5 years of age. Radiographically, they often enhance with gadolinium and sometimes extend through the foramen magnum. Symptoms are related to location; for example, tumors in the fourth ventricle may cause hydrocephalus and those in the area postrema may cause vomiting. There is no agreement with respect to grading. Variants include a *well differentiated ependymoma* and a more aggressive *malignant ependymoma*. In the past, the *ependymoblastoma* was classified as a malignant ependymoma but is now classified as a primitive neuroectodermal tumor (PNET).

The mainstay of treatment is surgery. If the tumor has leptomeningeal dissemination at diagnosis, surgery is palliative. Extent of resection is one of the most important predictors of outcome. Focal radiation is standard treatment after surgery, although some are studying whether radiation can be eliminated for patients with a complete resection. Chemotherapy is being investigated; responses have been seen to platinum agents. Most recurrences are focal. Two types have a better prognosis: *myxopapillary ependymoma*, arising from the filum terminale; and *subependymomas*, originating in the walls of the fourth or lateral ventricles. Histologically, subependymomas have features of both astrocytic and ependymal differentiation.

NEURONAL TUMORS AND MIXED NEURONAL-GLIAL TUMORS

Ganglioglioma

The most common mixed neuronal-glial tumor, gangliogliomas are usually slow-growing lesions in children and young adults; the most common location is the temporal lobe. Presentation is usually a progressive seizure disorder. Histologically, one finds both astrocytic and neuronal components; the glial component is usually astrocytic, and anaplastic degeneration is usually found in this component of the tumor. Surgery is the preferred treatment. Results of radiotherapy are not conclusive. Long-term survival after gross surgical resection is excellent. Malignant transformation is rare.

Desmoplastic Infantile Ganglioglioma

These tumors are rare and occur mostly in infancy. Patients experience seizures or show an increase in head circumference. Tumors are large, cystic, and located in the frontal and parietal lobes; they also have a cortical component that enhances intensely on MRI. There is moderate edema. Prognosis is excellent after surgery.

Gangliocytoma

Gangliocytomas are slow-growing and well-circumscribed. A variant is the *dysplastic gangliocytoma of the cerebellum* (Lhermitte-Duclos disease). The age at diagnosis is in the third decade. Most patients show signs of increased intracranial pressure or cerebellar dysfunction. Histologically, there is disruption of normal architecture, and it is often difficult to determine tissue planes. Prognosis is good if the tumor can be resected.

Ganglioglioneurocytomas

These tumors consist of small mature neoplastic neurons (neurocytes), large mature neoplastic neurons (gangliocytes), and astrocytes. In all of these, small cells are surrounded by clear cytoplasm and may be mistaken for oligodendrogliomas. Immunohistochemistry and electron microscopy show that these two tumors are separate entities. Electron microscopy confirms the neuronal origin of ganglioglioneurocytomas, showing cells with neuronal processes, neurosecretory vesicles, and microtubular cytoskeletons. All subtypes have an indolent behavior, but recurrences can occur, especially with the white matter variants. Treatment is surgery.

Neurocytomas

Composed of mature neurons, neurocytomas are typically located within the ventricles (Fig. 55.7). Central neurocytomas are located outside the ventricles and are usually found in young adults. Tumors are well demarcated and may calcify. Histologically, there is a homogenous arrangement of uniform cells in a fibrillary matrix analogous to that of oligodendrogliomas. Prognosis is favorable after surgery. Actuarial 5-year survival is 81%. There may be malignant variants. The role of radiotherapy remains controversial and may be considered in cases of subtotal excision. Chemotherapy may be of benefit in recurrent tumors.

FIG. 55.7. Intraventricular neurocytoma. Gadolinium-enhanced MRI scan of 24-year-old woman with a 1-year history of headaches owing to a right lateral ventricular neurocytoma producing obstruction of the foramen of Monro. The tumor was completely resected.

Dysembryogenic Neuroepithelial Tumors

These rare tumors usually develop in children or young adults with a long history of seizures. They arise from a cortical location in the temporal lobe and only rarely require therapy other than surgical resection.

Primitive Neuroectodermal Tumor

PNET is a term used to designate tumors derived from primitive progenitor cells. These are aggressive neoplasms, usually occurring in children. Common histologic features are a high mitotic rate, high cellularity, and a tendency for leptomeningeal dissemination. Radiographically, PNETs appear aggressive and infiltrate the adjacent brain; contrast enhancement is common. *Medulloblastomas* are the most common type. Most are located in the cerebellar vermis but may also be observed in the hemispheres, particularly in adults. Leptomeningeal involvement is common. Treatment is usually a combination of surgery, craniospinal radiation, and chemotherapy. *Neuroblastomas* are rare, occur in children, and favor the frontoparietal lobes. They are large and cystic, and appear separate from adjacent brain. *Olfactory neuroblastoma (esthesioneuroblastoma)* is thought to arise from the olfactory neuroepithelial cells in the nasal cavity. Patients experience epistaxis or nasal obstruction. Surgery alone is the treatment for low-grade tumors, but higher grade requires multimodality treatment. High-grade lesions can benefit from cisplatin-based chemotherapy, but prognosis is dismal even with radiation, surgery, and chemotherapy. Long-term follow-up is mandatory.

[Primary Central Nervous System Lymphoma](#)
[Primary Central Nervous System Lymphoma in the Immunocompromised Patient](#)
[Intravascular Lymphoma](#)
[Cerebral Lymphoid Granulomatosis](#)
[Suggested Readings](#)

SYSTEMIC LYMPHOMA

Lymphoma secondarily involves the central nervous system (CNS) in up to 10% of patients and in 1% of those at the time of diagnosis. The leptomeninges (76%), nerve roots (36%), CNS parenchyma (31%), and dura (14%) are commonly affected. The primary tumor is usually non-Hodgkin lymphoma (NHL), including diffuse poorly differentiated lymphocytic lymphoma in the original Rappaport classification or, in the modified version, lymphoblastic lymphoma and Burkitt lymphoma; nodular types usually convert to diffuse types before involving the CNS. For *Hodgkin disease*, the pattern differs with leptomeningeal disease or epidural cord compression; intracerebral lesions are rare.

A typical scenario is one of a progressive systemic lymphoma that does not respond to therapy. The median survival is 9 weeks; 1-year survival is 12%. The cause of death is usually progressive systemic disease. Prognosticators of decreased risk for CNS relapse are age less than 30 years, stable systemic disease, and lack of bone marrow involvement. Some authors recommend CNS prophylaxis for high-risk groups, including T-cell lymphomas and Burkitt lymphomas. NHL has been rarely associated with primary angitis of the CNS; remission may accompany treatment for the lymphoma.

Meningeal involvement is seen in 4% to 8% or higher for some histologic subtypes. Symptoms include visual disturbances (39%), headache (29%), weakness (29%), drowsiness or confusion (21%), nausea and vomiting (18%), numbness (8%), or back pain (2%); 5% have no symptoms. Sixty percent of patients have cranial nerve palsies, 34% spinal nerve or root signs, and 24% behavioral changes. The oculomotor, abducens, and facial nerves are most commonly affected. Seventy-nine percent of the cerebrospinal fluid (CSF) examinations show tumor cells on the first spinal tap. A completely normal CSF is rare. Lymphoblastic or small noncleaved cell histology, age under 40 years, and stage IV disease are all associated with a high probability of leptomeningeal disease. Patients with three risk factors have an estimated probability of involvement of 50% at 12 months. At the time of leptomeningeal disease, up to 84% of patients have progressive systemic NHL or concomitant systemic relapse, 60% have bone marrow involvement, and 86% of patients can achieve a complete remission with irradiation and chemotherapy but median survival is 71 days.

Spinal cord involvement occurs in 6% of patients and appears as epidural disease. Magnetic resonance imaging (MRI) shows single, homogeneous, and isointense lesions that affect one to four vertebral segments. Paravertebral soft tissue masses communicate with the epidural lesions through the neural foramina. Enhancement is nonspecific. Diffuse marrow replacement is common, but not vertebral collapse. Predilection for the thoracic cord is well known. Extension from the periaortic lymph nodes may be a mechanism of spread. Patients have backache with signs of spinal cord or radicular compression.

Dural involvement is rare; 38 cases have been reported. The most common site is the thoracic spine, followed by the cervical spine and brain. CSF can be abnormal even with negative cytology. Twenty percent are low-grade lymphomas and 80% high-grade lymphomas, most of B-cell lineage. The systemic lymphoma is usually in remission at the time of dural symptoms. Treatment is with local radiation. Median survival is 26 months after diagnosis for patients treated with both surgery and radiation.

PRIMARY CENTRAL NERVOUS SYSTEM LYMPHOMA

Epidemiology

Primary central nervous system lymphoma (PCNSL) accounts for less than 2% of all CNS neoplasms and 7% of all malignant lymphomas. The incidence is on the rise, both in the immunocompromised and the immunocompetent populations, more than what can be attributed to improved diagnosis by better imaging. A threefold increase has been observed in immunocompetent people. The peak incidence is the fifth to seventh decade, with a male to female ratio of 3:2. A peak in the first decade of life is a measure of children with acquired immunodeficiency syndrome (AIDS).

Clinical Manifestations

These are nonspecific. The most common symptoms are those related to an intracranial mass; an encephalitic-like picture; strokelike presentation, resembling demyelination disease; or cranial nerve palsies. Patients with PCNSL and AIDS tend to have more constitutional signs.

Pathology

The tumor was first described at the beginning of the century and called *perivascular sarcoma* or *reticulum cell sarcoma*. In 1974, the cells were recognized as transformed lymphocytes and the term PCNSL was introduced. The neoplastic cells of PCNSL and NHL have the same origin. Theories on pathogenesis include migration of lymphocytes to the CNS secondary to infection or inflammation or activation of lymphocytes that have a specific CNS predilection.

Many classifications have been proposed. PCNSL is classified as extranodal diffuse histiocytic lymphoma in the Rappaport classification or as large cell or immunoblastic lymphoma in the Working Formulation. Most are large B-cell variants; 5% are T cell in origin. The tumors contain pleomorphic B cells mixed with reactive T cells, recruited as a host response to the tumor. Up to 60% of the non-human immunodeficiency virus (HIV) PCNSL are diffuse large cell forms, but about 20% are small to medium sized. Polymerase chain reaction analysis of gene rearrangement may help determine monoclonality, although up to 16% of both AIDS and non-AIDS PCNSL display biclonal immunoglobulin light chains.

There are four pathologic manifestations. Intraaxial masses, commonly hemispheric, are the most common. Diffuse meningeal or periventricular involvement is seen in 24% of cases. The tumor can have a purely meningeal distribution, or primary leptomeningeal lymphoma. Uveal or vitreous lesions may be the first site of disease, as are intradural spinal metastases. A rare manifestation is the primary intramedullary lymphoma of the spinal cord. The tumors are firm and nodular, surrounded by edema and spread to the leptomeninges or subpial region. PCNSL is multifocal in 50% of cases. Histologically, the cells are closely packed, infiltrate surrounding brain, and have a characteristic perivascular concentration. Necrosis and hemorrhage are most common in tumors of immunocompromised patients. The pathogenesis is obscure. Epstein-Barr virus (EBV) may induce B-cell clone transformation. EBV genome has been found in the tumor of up to 100% of immunocompromised patients, in contrast to 16% of PCNSL in immunocompetent individuals, where EBV may not play an important role in pathogenesis.

Diagnosis

Diagnosis usually requires tissue, CSF, or aqueous humor (by vitreous examination). Corticosteroids induce a temporary resolution of the lesion in up to 60% of patients. Multiple contrast-enhancing lesions that recur rapidly after tapering the corticosteroid dosage should be suspicious. The incidence of leptomeningeal disease at diagnosis varies from 12% to 66%. CSF shows malignant cells in up to 43% of patients. Extent of disease workup includes neuroophthalmologic examination, contrast MRI of the spine, and lumbar puncture. Twenty percent of patients have ocular lesions at diagnosis. Both infectious and lymphomatous meningitis may coexist. The CSF shows a reactive pleocytosis in infectious meningitis, whereas monoclonal B lymphocytes are seen in lymphomatous meningitis.

Imaging

The lesions may be single or multiple and are often periventricular. The most common location is supratentorial; the posterior fossa is less favored. Fifty-five percent

appear in the white matter or corpus callosum; 17% in the deep gray matter, basal ganglia, or hypothalamus; 11% in the posterior fossa; and 1% in the spinal cord. Lesions are hypodense but may be iso- or hyperintense on computed tomography (Fig. 56.1A). On MRI the lesions are round, oval, or gyral, usually hypointense relative to the gray matter on T1 images. On T2, they appear hypointense to isointense to the gray matter, a pattern attributed to an increased nuclear-to-cytoplasmic ratio. T2 changes help to differentiate PCNSL from gliomas or demyelination, which appear hyperintense (Fig. 56.2C). Contrast enhancement is dense and homogeneous in immunocompetent patients (Fig. 56.1, Fig. 56.1B and Fig. 56.1C, and Fig. 56.2, Fig. 56.2A and Fig. 56.2B).

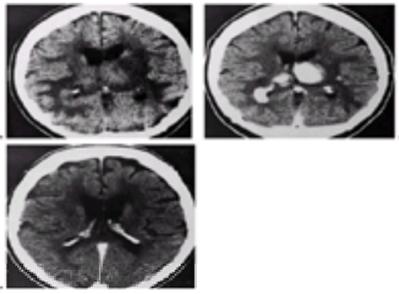

FIG. 56.1. **A:** Noncontrast computed tomography (CT) showing isodense bilateral thalamic lesions with white matter edema. **B:** Contrast-enhanced CT showing marked enhancement of diffuse lymphoma. Intraventricular tumor is also present. **C:** Contrast-enhanced CT 2 months after radiation therapy (with 5,000 cGy to the whole brain) is normal except for persistence of white matter lucency.

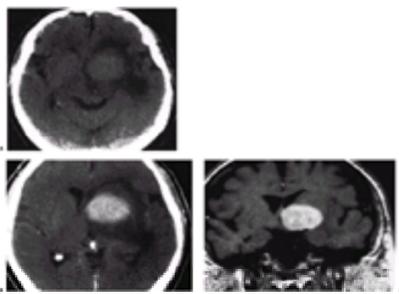

FIG. 56.2. Primary central nervous system lymphoma. Noncontrast-enhanced (**A**) and contrast-enhanced (**B**) axial computed tomographies and contrast-enhanced coronal magnetic resonance image (**C**) show large left basal ganglionic primary central nervous system lymphoma.

The borders are not well demarcated. Mirror-image bilateral-enhancing lesions in the basal ganglia are pathognomonic but rare. MRI can show diffuse ependymal spread that is not appreciated on computed tomography (Fig. 56.3, Fig. 56.3A and Fig. 56.3B). Ring enhancement, calcification, and hemorrhage are uncommon. The differential diagnosis includes high-grade gliomas, abscess, sarcoid, tuberculosis, or active areas of demyelination. Edema on MRI is moderate to severe in abscesses or metastases and mild to moderate in PCNSL, a difference that aids diagnosis.

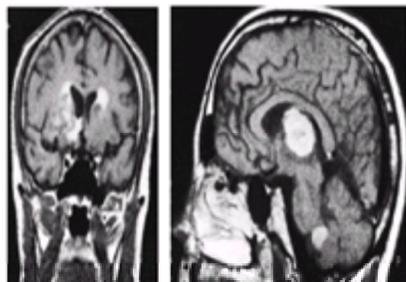

FIG. 56.3. Primary central nervous system lymphoma (PCNSL): ependymal spread. **A:** Contrast-enhanced coronal magnetic resonance image of a patient with progressive cognitive impairment and diabetes insipidus shows bilateral periventricular and hypothalamic lesions that enhance markedly after contrast administration. **B:** Sagittal contrast-enhanced magnetic resonance image of a different patient with gait ataxia caused by fourth ventricular spread of a thalamic PCNSL.

Treatment

Corticosteroids

Response is dramatic, with a decrease in edema and a cytotoxic effect on lymphoma cells. Up to 10% of lesions disappear, sometimes lasting months after steroids have been discontinued. A biopsy taken after corticosteroid therapy has started may yield falsely negative results. Corticosteroid treatment for a suspected lesion is strongly contraindicated. Response to steroids is not pathognomonic because demyelinating conditions or sarcoidosis may behave similarly.

Surgery

Because the tumors are infiltrative and sometimes bilateral, surgical resection is not the mainstay of treatment. The goal of surgery is to provide tissue diagnosis; it does not prolong survival.

Radiation

PCNSL is characterized by high responses to radiation. Patients receive 180 cGy per fraction, for a total of 60 Gy. The median survival is 10 to 18 months; only 3% to 4% live 5 years with this treatment alone. Age less than 60 years and Karnofsky performance better than 70 are prognosticators of better outcome.

Chemotherapy

PCNSL is a chemosensitive tumor. The malignant lymphocytes infiltrate the intact brain and agents must reach all areas at risk. Up to 100% of patients have leptomeningeal disease at autopsy, so chemotherapy addressing this compartment is an important component of treatment. Methotrexate crosses the blood-brain barrier, and therapeutic CSF concentrations are seen after intravenous administration. Methotrexate-based regimens are more effective than cyclophosphamide, vincristine, adriamycin, and prednisone (CHOP), which is the traditional treatment for systemic lymphoma. Glass et al. (1996) treated 25 patients with high-dose maintenance intravenous methotrexate alone (more than 3.5 g/m² for one to six cycles). Eighty-two percent had a complete response, and the median survival of 42

months for the responding group compared favorably with regimens using multiple agents, with less toxicity; the Karnofsky performance improved.

Elderly patients are particularly prone to the neurotoxic effects of irradiation and may benefit from these chemotherapy-only regimens. Cytosine arabinoside in high doses achieves therapeutic levels in both brain parenchyma and CSF; it has also been used to treat ocular disease. Excellent responses have been observed to a regimen consisting of carmustine, methotrexate, procarbazine, and dexamethasone. Chemotherapy alone, using a combination of agents, can lead to remission of intraocular lymphoma without radiotherapy.

Disruption of the blood–brain barrier followed by chemotherapy has led to prolonged survival. Newell et al. (1991) administered methotrexate, cyclophosphamide, and procarbazine, achieving a median survival of 44 months without radiotherapy. High-dose chemotherapy followed by bone marrow/stem cell support is an accepted treatment for relapsed systemic NHL. The regimen of BCNU, etoposide, cytarabine, melphalan, followed by bone marrow reconstitution, is widely used for non-NHL and may be used for PCNSL in the future.

Combination Therapy

Several reports suggest that the combination of chemotherapy and radiation improves outcome over radiation alone, but this has not been observed in all series. DeAngelis and associates (1992) achieved a 41-month median survival with intravenous (1 g/m^2) and intrathecal methotrexate, radiotherapy, followed by intravenous cytosine arabinoside. Acute toxicity was minimal. Similar results have been observed with radiotherapy followed by intraventricular methotrexate and CHOP; procarbazine, CCNU, and vincristine; or vincristine, cyclophosphamide, prednisolone, and doxorubicin.

Prognosis

PCNSL is still a therapeutic challenge. The median survival for patients treated with combination regimens is 42 months, whereas for those treated solely with irradiation it is 12 to 18 months. Fifty percent of patients relapse, usually within 2 years of diagnosis and mostly at distant sites. Leptomeningeal or spinal cord recurrence occurs in 60%. Extraneural spread is rare but can involve the lymph nodes, heart, gastrointestinal tract, and bone marrow. About one-third of patients treated with chemotherapy and radiation have a syndrome of progressive ataxia, dementia, and urinary incontinence, which appears after a median of 13.2 months from diagnosis. A ventriculoperitoneal shunt may provide benefit. Other patients develop cerebrovascular disease, which may be related to treatment or to the disease itself. Delayed leukoencephalopathy is seen in 80% of patients older than 60 years who survive 1 year.

PRIMARY CENTRAL NERVOUS SYSTEM LYMPHOMA IN THE IMMUNOCOMPROMISED PATIENT

Epidemiology

The immunocompromised states associated with PCNSL include renal transplantation, Wiskott-Aldrich syndrome, ataxia telangiectasia, IgA deficiency, rheumatoid arthritis, progressive multifocal leukoencephalopathy, and IgM paraproteinemic neuropathy. PCNSL is the most common brain tumor in patients with AIDS, developing in 1% to 3% of all patients. Typically, patients have profound immunosuppression and marked T4 cell depletion (median CD4 counts are less than $50/\mu\text{L}$). At autopsy, 75% of patients with AIDS harbor PCNSL. In immunosuppressed subjects, lymphoma is symptomatic in the third or fourth decades. About 2% of renal transplant patients develop PCNSL, 100 times more than the general population.

Pathology and Pathogenesis

Transplant and HIV-related lymphomas are generally polyclonal high-grade B-cell lymphomas, whereas in the immunocompetent population they are intermediate grade. EBV may play a role in the induction of PCNSL, and molecular analysis has helped in understanding the steps to lymphocytic transformation. About 100% of HIV-related PCNSL are positive for EBV markers, whereas PCNSL in nonimmunocompromised patients are rarely positive for EBV. In the African Burkitt lymphoma, EBV genes are expressed in all the tumor cells. An immunosuppressed host has little immunity to EBV infection. A portion of the host's lymphocytes then become chronically infected, and the B-lymphocytic cell line becomes immortalized. The infected cells undergo expansion into clones of lymphocytes that eventually produce a lymphoma. The CNS may be a site of predilection. The more profound the immunosuppression, the greater the likelihood that a chronic EBV infection will result in a lymphoma. The EBV infection, or the chronic stimulation of B cells, then leads to oncogene activation, which further allows the proliferation of the lymphoma. Coinfection of the CNS with CMV has been observed, further suggesting a role for infection in AIDS-related PCNSL.

Some lymphomas in immunocompromised patients follow polyclonal proliferation of B cells. The *lymphoproliferative disorders*, although possibly fatal, are not monoclonal and thus do not fit the strict definition of lymphoma. When immunosuppression is decreased, the tumor may recede.

Diagnosis

The time from seroconversion to PCNSL is about 2 years. In 10% of patients, the symptoms of PCNSL led to the diagnosis of AIDS. About 56% of patients have focal signs or symptoms compared with 27% of patients with PCNSL and no HIV disease; this may be due to more rapid progression in people with AIDS. Many patients have concurrent opportunistic infections. The standard of practice for an HIV-positive patient and a cerebral mass is treatment with antitoxoplasmosis medication. If there is no clinical or radiographic response after 2 weeks, tissue diagnosis is considered, via brain biopsy, lumbar puncture, or vitreous examination. Immunocompromised patients with a single lesion are more likely to have PCNSL, and early biopsy is advocated. PCNSL may coexist with cerebral toxoplasmosis, and radiographic improvement may follow antitoxoplasmosis treatment even in patients who are later found to have a PCNSL. Positron emission tomography may help differentiate neoplastic from nonneoplastic conditions. CSF can be analyzed for EBV by polymerase chain reaction studies. The gold standard for diagnosis is still tissue histology.

Radiography

The tumor may have irregular ringlike contrast enhancement (corresponding to necrosis), and it may be difficult to distinguish the lesion from toxoplasmosis. An irregular type of enhancement is more commonly associated with PCNSL, whereas smooth enhancement is associated with toxoplasmosis. Cytomegalovirus ependymitis can mimic PCNSL.

Treatment

The standard treatment is whole brain radiation. Some report prolonged survival in selected patients treated with both chemotherapy and radiation. The best candidates are those with limited disease (i.e., no leptomeningeal metastases), good performance status, no coexisting medical conditions, and a CD4 count greater than $200/\text{mm}^3$. The optimal dose of radiation is not known. A regimen of 150 cGy per fraction to a total dose of 40 Gy and a boost of 20 Gy to the tumor bed has been recommended for patients with no other AIDS-related illnesses. For those with other AIDS-related illnesses, 200 cGy per fraction to a total dose of 54 Gy has been recommended. Most patients have a clinical response to radiotherapy. All patients should have a CSF examination to determine spinal seeding. If so, MRI of the spine can detect bulky disease that may need radiotherapy. Combined regimens of chemotherapy and radiation have shown mixed results because of the limited bone marrow reserve. Some new regimens have attempted to use low-dose chemotherapy and radiation, and these have better results than more aggressive regimens with higher doses of chemotherapy. Treatment also includes an attempt to reduce the immunosuppressive state.

Prognosis

The median survival after diagnosis is 1 to 2 months with supportive care alone and 2 to 6 months with radiation. Survival correlates closely with Karnofsky performance before treatment, length of time since seroconversion, and the presence of more than one risk factor for HIV. Patients who have radiation therapy commonly die of opportunistic infections, whereas patients who do not receive radiation usually die of the tumor.

A View of the Future

There are several unanswered questions. How can a tumor of neoplastic lymphocytes occur in an organ without endogenous lymphoid tissue? Why is the tumor so exquisitely radio- and chemosensitive, only to recur months after a complete response to treatment has been observed? Why does PCNSL fail at distant sites even if

the initial site of disease is free of tumor? The optimal drugs, best treatment reschedule, or ways to minimize long-term treatment-related sequelae still need to be determined. Because of the long-term sequelae of whole brain irradiation, new treatment regimens may attempt to achieve durable responses, delaying radiation until recurrence, or eliminating it altogether. It is not clear whether high-dose intravenous chemotherapy alone could treat leptomeningeal disease or how much treatment can prevent leptomeningeal failures.

INTRAVASCULAR LYMPHOMA

This rare condition was first described in 1959 by Pflieger and Tappeiner; it is characterized by angiotropic growth, with predilection for the skin and CNS. The disease is considered a form of B-cell NHL and is also called *neoplastic angioendotheliomatosis* or *angiotropic lymphoma*. There are three main forms: a mild cutaneous form, a progressive form with both skin and visceral organ involvement, and an aggressive form with multiorgan involvement.

Diagnosis usually requires a brain biopsy. Pathologically, neoplastic cells are seen within and occlude the lumen of the capillaries, venules, arterioles, and small arteries. Only rarely do neoplastic cells extend beyond the vessel wall. Blood vessels in the subarachnoid space, cortex, white matter, and deep gray matter are involved. Immunoperoxidase staining is positive for B-cell markers. The cells may have surface properties that favor attachment to the blood vessels, skin, CNS, and peripheral nerves, differing from sites of involvement of lymphoma. White matter changes are characterized by axonal degeneration, loss of myelin, and macrophage infiltration. Bone marrow is spared. Because of the nonspecific clinical features and nonspecific imaging characteristics, the disease is often found only at autopsy, with dissemination to skin, adrenals, and brain. Polymerase chain reaction assay for rearrangement of immunoglobulin heavy chain genes can confirm the presence of a monoclonal B-cell population.

Clinically, the symptoms are nonspecific and usually develop over weeks or months. A strokelike syndrome can occur, but progressive encephalopathy is the most common manifestation, present in up to 82% at some time. Superimposed focal signs include hemiparesis (39%), myelopathy (34%), and aphasia (9%). Typically, a patient with multiple transient ischemic attacks or embolic strokes develops progressive dementia. Unexplained fever is seen in 25% of patients. Weight loss is common. The median age at onset is 60 years (range, 12 to 87 years). Systemic signs are rare. The condition may mimic systemic necrotizing vasculitis. Skin lesions include telangiectasias, hemorrhagic nodules, and leg lymphedema. The syndrome often occurs during the sixth or seventh decade of life, and the male to female ratio is usually 2:1. Average survival ranges from 9 to 12 months.

Laboratory results are mostly normal. Anemia is seen in up to 73% of patients, elevated erythrocyte sedimentation rate in 83%, and elevated lactate dehydrogenase in 89%. CSF protein is increased in 90% of patients, with 10 white blood cells/mm³ in 57% and oligoclonal bands in 77%. Neoplastic cells in the CSF are rare (3%).

Imaging is nonspecific. Abnormalities are multifocal, reflecting diffuse brain involvement. The most common abnormality is a masslike lesion with increased signal on T2-weighted images, which correlates with areas of gliosis and edema pathologically. The white matter is most commonly affected, but lesions can also be seen in the gray matter. Infarctlike lesions are multifocal with gyriform enhancement. There may be enhancement along the corpus callosum. Meningeal enhancement results from direct infiltration of vessels, meningeal microinfarcts, or sluggish flow through that area. Angiography may show multifocal vessel stenosis or occlusion, as in vasculitis. Other conditions that may mimic this disease include multiinfarct dementia, vasculitis, Creutzfeldt-Jakob disease, progressive multifocal leukoencephalopathy, or gliomatosis cerebri.

Treatment has included corticosteroids, cyclophosphamide, a combination of chemotherapy (CHOP-like regimens) and radiation, plasmapheresis, and intrathecal chemotherapy. Although complete responses have been observed, median survival is only 6 months. Spontaneous remission is rare.

CEREBRAL LYMPHOID GRANULOMATOSIS

This is an angiocentric lymphoproliferative process that preferentially involves the lungs. It was first described in 1972 by Liebow. The diagnostic triad includes a lymphoid infiltrate, angiitis (blood vessel infiltration), and granulomatosis (lesion necrosis). Extrathoracic manifestations include the skin (37%) and the CNS (30%). Neurologic complications lead to CNS symptoms in 65% of the patients: headache, altered consciousness, and cranial nerve palsies or a multiinfarct dementia. Peripheral neuropathy affects 25%. Radiographically, lesions are seen in the gray and white matter, accompanied by edema. Meningeal thickening and linear punctate enhancement in the brainstem can be seen. Pathologically, there is a lymphoid infiltrate (plasma cells, histiocytes, and lymphoreticular cells), with vascular proliferation and necrosis. The perivascular spaces are infiltrated with neoplastic cells, differing from the angiotropic lymphoma, where the neoplastic cells are within the vessel lumen. Lung findings are similar. Prognosis is poor; median survival is about 2 years. Ultimately, many patients develop lymphoma, and some investigators consider this an angiocentric T-cell malignancy. A classification has been developed for purposes of treatment: Grade I lesions may not develop into aggressive malignancies, and grades II and III lesions warrant intensive chemotherapy. The EBV genome has been found in most grade II lesions, suggesting that EBV, contrary to earlier views, can transform and infect T cells.

Among central nervous system (CNS) tumors, the widest variety of pathologic types occurs in the region of the pineal gland and posterior third ventricle ([Table 57.1](#)). The numerous cell types that make up the normal gland and surrounding periventricular region contribute to these diverse histologic subtypes. The pineal gland is composed of glandular tissue, glia, endothelial cells, and sympathetic nerve terminals. Pineal cell tumors and pineoblastomas arise from pineal glandular elements, astrocytomas and oligodendrogliomas from glial cells, hemangioblastomas from endothelial cells, and chemodectomas from sympathetic nerve cells. Arachnoid cells in the reflections of the tela choroidea adjacent to the pineal gland give rise to meningiomas. Ependymomas arise from ependymal cells that line the third ventricle. Germ cell tumors (GCTs) derive from primitive germ cell rests that are retained in the pineal and other midline structures after embryologic migration courses.

Type	Benign	Malignant	Male : female	Average age (yr)
Germ cell	13	51	58/6	20.2
Pineal cell	9	41	25/25	36.2
Glial cell	19	34	27/26	25.6

Total	64	131	123/72	29.3

TABLE 57.1. SUMMARY OF PATHOLOGICALLY VERIFIED PINEAL TUMORS AT THE NEW YORK NEUROLOGICAL INSTITUTE (1978–1998)

Pineal tumors account for approximately 1% of all intracranial tumors in the United States. In Asia, where GCTs are endemic, pineal cell tumors constitute 4% to 7% of all intracranial tumors.

GERM CELL TUMORS

GCTs account for approximately one-third of all pineal tumors and are histologically identical to gonadal GCTs with a predominance in men and younger age groups. Extragonadal GCTs (including pineal region) have a poorer prognosis than gonadal GCTs. GCTs range along a spectrum from benign (as in teratomas, dermoids, epidermoids, and lipomas) to highly malignant (as in choriocarcinomas, embryonal cell carcinomas, teratocarcinomas, and endodermal sinus tumors).

Germinomas are tumors of an intermediate degree of malignancy arising from primordial germ cells that can occur in the gonads or in midline sites in the nervous system (pineal and suprasellar region) or body (mediastinum and sacrococcygeal region). Although histologically identical in all sites of origin, by conventional nomenclature germinomas in the testes are called *seminomas*, those in the ovaries are *dysgerminomas*, and those in the CNS are *germinomas* (previously called atypical teratomas).

Unlike suprasellar GCTs, which show no sexual predisposition, GCTs of the pineal region occur predominantly in males. Germinomas are most common in boys in the first or second decade and have a propensity to seed the cerebrospinal fluid (CSF) pathways. Despite their malignant characteristics, germinomas are exquisitely sensitive to radiotherapy and chemotherapy; they can be cured in many patients. The presence of beta human chorionic gonadotropin (b-hCG) in a germinoma implies a slightly worse prognosis.

Embryonal cell carcinomas, choriocarcinomas, and endodermal sinus tumors are rare but highly malignant GCTs that may metastasize to the CSF. Choriocarcinoma contains cyto- and syncytiotrophoblastic cells that produce b-hCG. Endodermal sinus tumors contain yolk sac elements that produce alpha-fetoprotein (AFP). High levels of b-hCG or AFP in the CSF or serum indicate the presence of malignant germ cell elements, and histologic confirmation is not necessary for treatment with radiation, chemotherapy, or both ([Table 57.2](#)). GCTs in general are difficult to classify because 25% are of a mixed type, containing both malignant and benign elements or several different malignant elements ([Table 57.3](#)). Extensive specimen sampling is necessary for accurate histologic determination. High AFP or b-hCG levels in the CSF trigger an extensive search for malignant germ cell elements even if the pathologic specimens suggest otherwise. Benign GCTs such as teratomas, dermoids, and epidermoids are generally curable with surgery alone. Teratomas are composed of tissues from three germ cell lines (endo-, ecto-, and mesoderm). Immature teratomas are a variant of this tumor that may grow quickly and behave in a malignant fashion, including CSF seeding.

Tumors	βhCG	AFP
Benign germ cell	–	–
Immature teratoma	?	+/-
Germinoma	–	–
Germinoma with syncytiotrophoblastic cells	+	–
Embryonal cell carcinoma	+/-	+/-
Choriocarcinoma	++	–
Endodermal sinus tumor	–	++

β-hCG: beta human chorionic gonadotropin; AFP, alpha-fetoprotein.

TABLE 57.3. PURE VS. MIXED GERM CELL TUMORS AT THE NEW YORK NEUROLOGICAL INSTITUTE (1978–1998)

PINEAL CELL TUMORS

Pineal cell tumors arise from pineocytes and range from histologically primitive pineoblastomas to well-differentiated pineocytomas. Attempts to correlate prognosis and survival with either variant have been inconclusive because both may behave in a malignant fashion, with recurring at the primary site and spreading through the CSF. Pineal cell tumors occur in children and young adults before age 40 with no sex predominance. They are occasionally found concurrently with retinoblastomas and may contain mixed cell types. The pineoblastomas are considered a variant of primitive neuroectodermal tumors. Pineal cell tumors are radiosensitive, but experience with chemotherapy is limited.

GLIOMAS

Gliomas, like GCTs, account for one-third of pineal tumors. Most are invasive and have a prognosis comparable with astrocytomas of the brainstem. About one-third of gliomas are low grade, cystic, and surgically curable. Anaplastic astrocytomas and glioblastomas are less common. Oligodendrogliomas and ependymomas may also occur. Treatment of these tumors is identical to the treatment of gliomas in other areas of the CNS.

MENINGIOMAS

Meningiomas can arise from the velum interpositum or from the tentorial edge with a higher incidence in middle age and the elderly. They are amenable to surgical resection.

METASTASIS AND OTHER MISCELLANEOUS TUMORS

The pineal gland does not have a blood–brain barrier and, like the pituitary gland, may be underrecognized as a possible site for CNS metastasis of systemic tumors. Miscellaneous tumors include sarcoma, hemangioblastoma, choroid plexus papilloma, lymphoma, and chemodectoma.

PINEAL CYSTS

Benign cysts of the pineal gland are often found incidentally on radiographic studies, and it is important to distinguish them from cystic tumors. They are normal variants of the pineal gland and consist of a cystic structure surrounded by normal pineal parenchymal tissue (Fig. 57.1). Radiographically they are up to 2 cm in diameter and often have some degree of peripheral enhancement that may be a compressed normal pineal gland. Pineal cysts may be found in 4% of all magnetic resonance images. These cysts are static anatomic variants and need no treatment unless they become symptomatic. In one series of 53 pineal cysts, fewer than 10% developed hydrocephalus requiring surgical intervention.

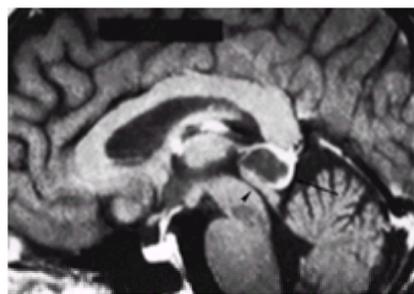

FIG. 57.1. Sagittal T1-weighted magnetic resonance image with gadolinium of a pineal cyst. These cysts can have rim enhancement (*arrow*) and can be up to 3 cm in diameter. They rarely cause compression of the Sylvian aqueduct (*arrowhead* on patent aqueduct) and are rarely symptomatic. Histologically, they are normal variants of the pineal gland and must be distinguished from cystic tumors and require no treatment. Growth of the cyst on serial magnetic resonance images or the development of hydrocephalus is sufficient cause to doubt the diagnosis, and surgical resection should be considered.

SYMPTOMS

Pineal region tumors can become symptomatic by three mechanisms: increased intracranial pressure from hydrocephalus, direct brainstem and cerebellar compression, or endocrine dysfunction. Headache, associated with hydrocephalus, is the most common symptom at onset and is caused by obstruction of third ventricle outflow at the aqueduct of Sylvius (Table 57.4). More advanced hydrocephalus can result in papilledema, gait disorder, nausea, vomiting, lethargy, and memory disturbance. Direct midbrain compression can cause disorders of ocular movements such as Parinaud syndrome (paralysis of upgaze, convergence or retraction, nystagmus, and light-near pupillary dissociation) or the Sylvian aqueduct syndrome (paralysis of downgaze or horizontal gaze superimposed upon a Parinaud syndrome). Either lid retraction (Collier sign) or ptosis may follow dorsal midbrain compression or infiltration. Fourth nerve palsies with diplopia and head tilt may be seen. Reversibility is a clue to pathogenesis; eye signs due to hydrocephalus recede promptly after ventricular shunting. Ataxia and dysmetria can result from direct cerebellar compression.

Symptoms	Number	Signs	Number
Headache	87	Parinaud syndrome	75
Nausea/vomiting	32	Ataxia	39
Gait unsteadiness	22	Papilledema	26
Diplopia	21	Normal exam	12

TABLE 57.4. PRESENTING SYMPTOMS AND SIGNS IN 100 CONSECUTIVE PATIENTS WITH PINEAL REGION TUMORS AT THE NEW YORK NEUROLOGICAL INSTITUTE

Endocrine dysfunction is rare, usually arising from secondary effects of hydrocephalus or tumor spread to the hypothalamic region. Diabetes insipidus occurs in less than 5% of pineal tumors, usually with a germinoma (Fig. 57.2). The symptoms may occur early, before any radiographic documentation of hypothalamic seeding. Although precocious puberty has been linked historically with pineal masses, documented cases are rare. Precocious puberty is actually precocious pseudopuberty because the hypothalamic-gonadal axis is not mature. It occurs strictly in boys with choriocarcinomas or germinomas with syncytiotrophoblastic cells and ectopic secretion of b-hCG. In boys, the luteinizing hormone-like effects of b-hCG can stimulate Leydig cells to produce androgens that induce development of secondary sexual characteristics and pseudopuberty. This phenomenon does not occur in girls with pineal region tumors because GCTs are rare in females; also, and more important, both luteinizing hormone and follicle-stimulating hormone are necessary to trigger ovarian estrogen production.

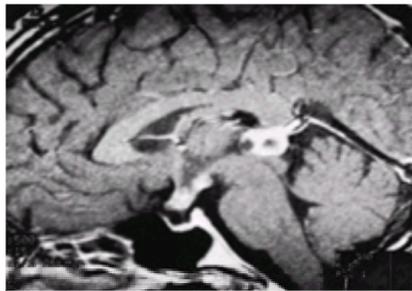

FIG. 57.2. Sagittal magnetic resonance image with gadolinium showing multicentric germinoma involving the pineal region and infiltrating the mammillary bodies, optic chiasm, and pituitary stalk. This patient presented with diminished visual fields and diabetes insipidus.

DIAGNOSIS

Magnetic resonance imaging (MRI) is the principal diagnostic test for pineal region tumors. MRI with gadolinium enhancement is mandatory for all pineal tumors to determine the presence of hydrocephalus and to evaluate tumor size, vascularity, and homogeneity. In particular, sagittal MRI reveals the relationship of the tumor to surrounding structures as well as possible ventricular seeding (Fig. 57.3). Computed tomography is complementary but does not provide as much information as MRI. Angiography is not performed unless a vascular anomaly is suspected. Measurement of AFP and b-hCG in serum and CSF is routine in the preoperative workup. If b-hCG or AFP levels are elevated, malignant germ cell elements are present even if histologic examination gives a benign impression, because a small island of these cells in a large tumor may be overlooked. Despite improved imaging and CSF markers, a definite histologic diagnosis cannot be made without pathologic examination of tumor tissue.

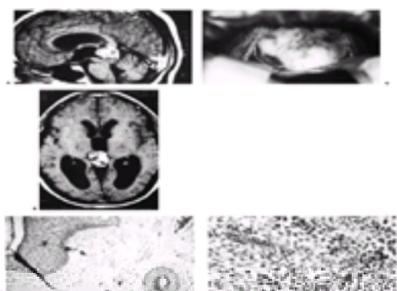

FIG. 57.3. Sagittal (A) and axial (B) magnetic resonance images with gadolinium of a mixed dermoid/germinoma causing hydrocephalus. C: Intraoperative photograph shows the tumor, which was completely resected through a supracerebellar-infratentorial approach without neurologic deficits (cerebellum is at the bottom of the photograph covered by a retractor). D and E: Histologic analysis revealed a mixed dermoid/germinoma.

SURGERY

Because of the wide variety of pineal region tumor subtypes, a histologic diagnosis is mandatory for optimal patient management (Fig. 57.4). The pineal region may be approached surgically from one of several variations, above or below the tentorium. Nearly one-third of pineal tumors are benign and curable with surgery alone. With malignant tumors, aggressive tumor resection provides the best opportunity for accurate histologic diagnosis and may increase the effectiveness of adjuvant radiotherapy or chemotherapy. The overall operative mortality is about 4%, with an additional 3% permanent major morbidity. The most serious complication of surgery is hemorrhage into a partially resected malignant tumor. The most common postoperative complications are ocular palsies, altered mental status, and ataxia; all are usually transient. For patients with obviously disseminated tumor or those with medical problems that pose excessive surgical risks, stereotactic biopsy is a reasonable alternative for obtaining diagnostic tissue. Although gaining in popularity, stereotactic biopsy is not performed routinely for these reasons: increased sampling error through insufficient tissue analysis, increased risk of hemorrhage from adjacent deep venous system and highly vascular pineal tumors, and the better prognosis that follows aggressive resection.

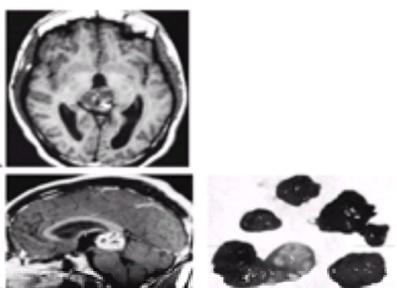

FIG. 57.4. Axial (A) and sagittal (B) magnetic resonance images with gadolinium of a heterogeneously enhancing pineal region tumor. The tumor comprised several germ cell elements, including immature teratoma, germinoma, endodermal sinus tumor, and embryonal cell carcinoma (C). Pineal region tumors can be extremely heterogeneous, and extensive tumor sampling is necessary to avoid diagnostic errors.

POSTOPERATIVE STAGING

All patients with pineal cell tumors, malignant GCTs, and ependymomas are thoroughly evaluated for CSF seeding even though this is a rare occurrence ([Fig. 57.5](#)). High-resolution MRI is more sensitive than computed tomography myelography. CSF cytology is not reliable in predicting seeding.

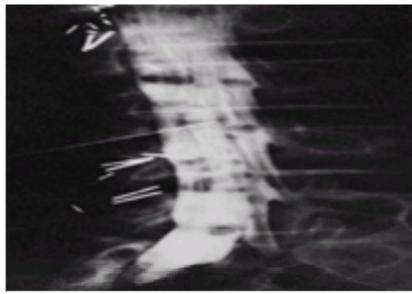

FIG. 57.5. Intradural seeding from a pineal tumor. Lumbar myelography, oblique view, demonstrates intradural filling defects studding the lumbar nerve roots. These represent "drop" metastases. (Courtesy of Drs. J.A. Bello and S.K. Hilal.)

RADIATION THERAPY

Radiation therapy consists of 4,000 cGy to the whole brain with an additional 1,500 cGy to the pineal region; it is recommended for all patients with malignant pineal region tumors. Spinal radiation is not recommended unless there is radiographic documentation of spinal seeding.

Radiosurgery for pineal tumors is promising, but experience is limited. It could be most useful for malignant pineal cell tumors and other small malignant tumors (less than 3 cm in diameter), particularly if combined with fractionated radiation. It may also be helpful for tumors that recur after radiation therapy. Germinomas historically have had an excellent response to external fractionated radiotherapy, and radiosurgery seems unlikely to improve upon those results.

CHEMOTHERAPY

Chemotherapy has been of most benefit with nongerminomatous malignant GCTs. The most commonly used regimens are combinations of cisplatin, vinblastine, and bleomycin or cisplatin and VP-16 (etoposide), which are usually given before radiation therapy. The results of chemotherapy alone may be comparable with those of radiation therapy for pure germinomas. There has been a trend to reduce radiation dosage because of long-term neurotoxicity by combining it with chemotherapy.

LONG-TERM OUTCOME

Generally, benign pineal tumors are curable with surgery alone. Among malignant tumors, the prognosis depends on the tumor histology ([Table 57.1](#)). Germinomas have a 75% to 80% 5-year survival with combined surgery and radiotherapy. Patients with a nongerminomatous malignant GCT rarely survive beyond 2 years, but this may improve with better chemotherapy. About one-third of astrocytomas are cystic tumors and are cured by surgery alone. Solid astrocytomas behave clinically like other brainstem gliomas and have a 67% 5-year survival rate. Radiation therapy is usually recommended for these tumors, but any effect on survival is difficult to evaluate. Among pineal cell tumors, a few are discrete, histologically benign, and completely resectable. Most malignant pineal cell tumors, however, are not resectable and have a 55% 5-year survival rate with surgery and radiation.

CHAPTER 58. TUMORS OF THE PITUITARY GLAND

JEFFREY N. BRUCE, MICHAEL R. FETELL AND PAMELA U. FREDA

[Pathology](#)
[Clinical Features](#)
[Radiographic Features](#)
[Differential Diagnosis](#)
[Treatment](#)
[Suggested Readings](#)

The true incidence of pituitary adenomas is difficult to ascertain because they are often asymptomatic; autopsy estimates range from 2.7% to 27%. There is no sexual predilection, but the tumors are most common in adults, peaking in the third and fourth decades; children and adolescents account for about 10%. These tumors are not hereditary except for rare families with multiple endocrine neoplasia, an autosomal dominant trait, manifested by a high incidence of pituitary adenomas and tumors of other endocrine glands.

PATHOLOGY

In the past, pituitary adenomas were classified by a now-obsolete system that identified them as acidophilic, basophilic, or chromophobic as determined by staining characteristics with hematoxylin and eosin. Growth hormone-secreting tumors were acidophilic adenomas, adrenocorticotrophic hormone-secreting tumors were basophilic adenomas, and chromophobic adenomas were thought to be nonsecretory. With improved immunohistochemistry, pituitary hormone secretion was detected within an adenoma, making it clear that the traditional histologic dyes are unreliable guides. The modern functional classification is based on endocrinologic activity, dividing tumors into secreting and nonsecreting types. Secreting tumors are less common and produce one or more anterior pituitary hormones, including prolactin (the most common endocrinologically active tumor), growth hormone, adrenocorticotrophic hormone, follicle-stimulating hormone, or luteinizing hormone. Mixed secretory tumors account for 10% of adenomas, and secretion of more than one hormone has implications for medical therapy. Some tumors secrete the alpha subunit of the large precursor molecules that form one of the polypeptide chains of glycoprotein hormones, even if the tumor is nonfunctional. "Null cell" adenomas or nonsecreting adenomas demonstrate no clinical or immunohistochemical evidence of hormone secretion.

For clinical purposes, pituitary adenomas are arbitrarily divided by size into *microadenomas* (less than 1.0 cm in diameter) or *macroadenomas* (more than 1.0 cm in diameter). When tumors erode the dura or bone, they are considered invasive and may infiltrate surrounding structures such as the cavernous sinus, cranial nerves, blood vessels, sphenoid bone, and sinus or brain. Locally invasive pituitary adenomas are nearly always histologically benign. Different staging systems have been based on degrees of invasion or extent, characteristics that are useful for prognosis and treatment ([Table 58.1](#)).

Grading system (Hardy and Vezina) based on radiologic characteristics
Grade I—microadenoma, remaining completely within the sella
Grade II—adenoma greater than 1cm, with expansion of the sellar floor but without perforating the floor
Grade III—perforation through the dura, with extension into the sphenoid sinus
Grade IV—diffuse infiltration of the sphenoid sinus and bone
Grade V—spread through the cerebrospinal fluid pathways
Grading system (Wilson) based on extrasellar extension
Stage 0—no suprasellar extension
Stage A—extension into suprasellar cistern only
Stage B—extension into anterior recess of third ventricle
Stage C—obliteration of anterior recess and deformation of floor of third ventricle
Stage D—intradural extension into anterior, middle, or posterior fossa
Stage E—extradural invasion into cavernous sinus

From Hardy J, Vezina JL. Transphenoidal neurosurgery of intracranial neoplasms. *Adv Neurol* 1976; 15:261-274; and Wilson CB, 1984.

TABLE 58.1. SUMMARY OF STAGING SYSTEMS FOR PITUITARY ADENOMAS

Pituitary carcinomas are extremely rare. They are highly invasive, rapidly growing, and anaplastic, but unequivocal diagnosis relies on the presence of distant metastases. Histologic appearance of pleomorphism and mitotic figures is insufficient to justify the diagnosis of carcinoma.

The posterior pituitary, which contains the terminal processes of hypothalamic neurons and supporting glial cells, is a rare site of neoplasia. *Infundibulomas* are rare tumors of the neurohypophysis; they are variants of pilocytic astrocytomas. *Granular cell tumors (myoblastomas or choristomas)*, also rare tumors of the neurohypophysis, are of uncertain origin.

Histologically, adenomas lose the typical acinar structure of the normal gland and may contain follicular, trabecular, or cystic portions or components growing as a diffuse sheet. Microscopically, the cells are arranged in a syncytial or sinusoidal pattern. Tumors often show small foci of hemorrhage or necrosis but usually no mitotic activity. Pituitary adenomas lack a discrete capsule, but the presence of a pseudocapsule facilitates surgical separation from adjacent normal glands.

CLINICAL FEATURES

Clinical manifestations stem from either endocrine dysfunction or mass effect with invasion or compression of surrounding neural and vascular structures. The manifestations and management of hormonally active tumors are discussed in [Chapter 146](#). Here, we limit discussion to nonsecretory tumors. Mass effects include headache, hypopituitarism, and visual loss. Headaches result from stretching of the diaphragm sella and adjacent dural structures that transmit sensation through the first branch of the trigeminal nerve. Visual loss may be accompanied by optic disc pallor, loss of central visual acuity, and visual field defects, but papilledema is rare. Visual field abnormalities are caused by compression of the crossing fibers in the optic chiasm, first affecting the superior temporal quadrants and then the inferior temporal quadrants. Further expansion compromises the noncrossing fibers and affects the lower nasal quadrants and finally the upper nasal quadrants ([Fig. 58.1](#)). Patients usually note blurring or dimming of vision. Formal visual field testing is important because some tumors affect only the macular fibers to cause central hemianopic scotomas that may be missed on routine screening. Although bitemporal hemianopia is most common, any pattern of visual loss is possible, including unilateral or homonymous hemianopia.

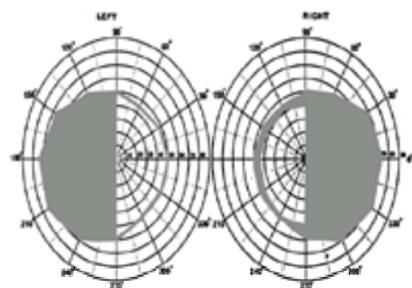

FIG. 58.1. Pituitary macroadenoma. Bitemporal hemianopia; visual acuity O.D. 15/200, O.S. 15/30. The blind half-fields are black. (Courtesy of Dr. Max Chamlin.)

Lateral extension of the tumor with compression or invasion of the cavernous sinus can compromise III, IV, or VI cranial nerve functions, manifesting as diplopia. The third cranial nerve is most commonly affected. There may be numbness in the V1 or V2 distribution. Overall, however, cranial nerve dysfunction is not a common feature of adenomas and may be more suggestive of other neoplasms of the cavernous sinus.

Adenomas may become enormous. Suprasellar extension may compress the foramen of Monro to cause hydrocephalus and symptoms of increased intracranial pressure. Hypothalamic dysfunction may be expressed as diabetes insipidus, although diabetes insipidus is relatively rare with adenomas and, if present, is more suggestive of conditions associated with inflammation or tumor invasion of the pituitary stalk. Extensive subfrontal extension with compression of both frontal lobes may cause personality changes or dementia. There may be seizures or motor and sensory dysfunction. Erosion of the skull base may cause cerebrospinal fluid (CSF) rhinorrhea.

Complete endocrine evaluation is necessary for all patients with pituitary tumors, not only to make the diagnosis of a secreting adenoma but also to determine the presence of hypopituitarism. Hypopituitarism may result from compression of the normal pituitary gland or blood supply; adequate replacement and long-term follow-up are then needed. Hormonal replacement most commonly includes thyroid and adrenal hormones. Nonsecreting tumors may be associated with slight elevations of serum prolactin levels to 100 mg/mL, which is attributed to compression of the pituitary stalk, interrupting dopaminergic fibers that inhibit prolactin release. Mild elevations are common and must be distinguished from prolactin-secreting tumors because bromocriptine has little or no effect on nonsecretory tumors.

In about 5% of pituitary tumors, the first symptoms are those of “pituitary apoplexy” due to hemorrhage or infarction of the adenoma. Symptoms include sudden onset of severe headache, oculomotor palsies, nausea, vomiting, altered mental state, diplopia, and rapidly progressive visual loss. Apoplexy is diagnosed by computed tomography or magnetic resonance imaging (MRI) and is usually an indication for emergency surgery ([Fig. 58.2](#)). Histologically, hematoxylin and eosin stains show massive necrosis of the adenoma.

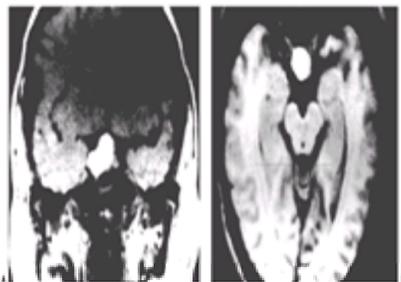

FIG. 58.2. Coronal (A) and axial (B) magnetic resonance images demonstrating a high signal pituitary mass that turned out to be a hemorrhage in a patient with apoplexy. This patient underwent a successful tumor resection through a standard transsphenoidal approach.

Pituitary adenomas may enlarge during pregnancy. Sometimes pregnancy is induced in a woman treated for infertility problems with an unrecognized pituitary adenoma.

RADIOGRAPHIC FEATURES

MRI is the best way to evaluate pituitary pathology, because soft tissue is identified without interference from the bony surroundings of the sella; MRI also produces images in any plane. Vascular structures such as the adjacent carotid artery are easily visualized by signal void. Normally, the anterior lobe of the pituitary gland has the same signal as white matter on T1-weighted imaging. With gadolinium, the normal gland enhances homogeneously. Small punctate areas of heterogeneity may be due to local variations in vascularity, microcyst formation, or granularity within the gland. The posterior lobe shows increased signal on T1-weighted images, probably representing neurosecretory granules in the antidiuretic hormone (ADH)-containing axons. The cavernous sinuses also enhance.

Microadenomas are sometimes difficult to see directly on MRI but may be inferred by glandular asymmetry, focal sellar erosion, asymmetric convexity of the upper margin of the gland, or displacement of the infundibulum ([Fig. 58.3](#)). The normal gland usually shows more enhancement than the microadenoma ([Fig. 58.4](#)). In the presence of a macroadenoma, the normal gland may not be visualized and the bright signal of the posterior lobe may be absent. Areas of increased signal on the T1-weighted image may be due to hemorrhage; areas of low signal may represent cystic degeneration. Although the cavernous sinus often appears expanded in the presence of a macroadenoma, it is difficult to distinguish invasion or compression from stretching of the cavernous sinus.

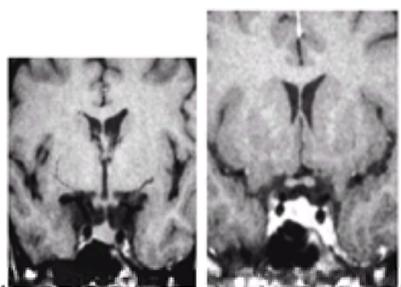

FIG. 58.3. Pituitary microadenoma. **A:** T1-weighted coronal magnetic resonance (MR) scan shows slight tilting of the pituitary stalk to the left, with questionable fullness of the right pituitary gland. These are secondary signs of pituitary microadenoma but are not sufficient to clinch the diagnosis radiographically. **B:** T1-weighted coronal MR scan after gadolinium enhancement demonstrates a tiny focus of relative hypointensity within the right pituitary gland. This is consistent with right-sided pituitary microadenoma. (Courtesy of Dr. S. Chan.)

FIG. 58.4. Pituitary adenoma. T1-weighted coronal magnetic resonance scan after gadolinium enhancement demonstrates a discrete focus of hypointensity in the right pituitary gland, most consistent with pituitary adenoma. (Courtesy of Dr. S. Chan.)

MRI alone is usually sufficient, but computed tomography may show the bony anatomy in better detail. MRI can usually exclude an aneurysm, but an angiogram is indicated if uncertainty exists.

DIFFERENTIAL DIAGNOSIS

Most lesions in the differential diagnosis have characteristic radiographic or clinical syndromes that distinguish them from pituitary adenoma. Craniopharyngiomas have a predilection for children, are calcified, and usually contain cystic areas that contain highly proteinaceous fluid with cholesterol crystals. Rathke cleft cysts are similar to craniopharyngiomas but have a cystic appearance without any solid component. Meningiomas are commonly found in the diaphragm sella, planum sphenoidale, and tuberculum sella and may be difficult to distinguish from a macroadenoma. Distinguishing characteristics of meningiomas include enhancement, visualization of a cleavage plane between the mass and the sellar contents, normally sized sella, and the presence of a dural "tail" of enhancement. Optic glioma, hypothalamic glioma, germinoma, dermoid tumor, metastasis, and nasopharyngeal carcinoma are less common entities to be considered. Chordomas characteristically show extensive clival bony destruction. Mucoceles of the sphenoid sinus may simulate pituitary adenoma. Visual symptoms and sellar enlargement may also result from chronic increased intracranial pressure of any origin. Characteristic signal voids on MRI usually distinguish an aneurysm. Differential diagnosis also includes sarcoidosis, lymphoma, lymphocytic hypophysitis, and other granulomatous diseases.

Herniation of the subarachnoid space into the sella through an incompetent diaphragm sella may produce the empty-sella syndrome with enlargement of the sella and flattening of the pituitary gland on the floor ([Fig. 58.5](#)). This syndrome may be associated with pseudotumor cerebri or CSF rhinorrhea. Although most are not symptomatic, an empty sella may be associated with headaches and, occasionally, mild hypopituitarism, but the visual fields are usually normal. The condition is readily seen on MRI and may follow previous transsphenoidal surgery.

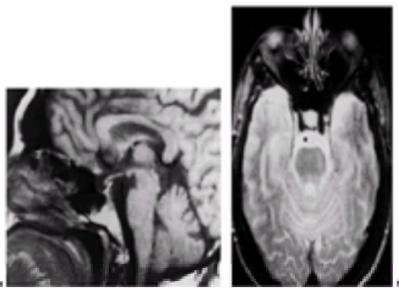

FIG. 58.5. Empty sella. **A:** Sagittal T1-weighted magnetic resonance (MR) scan demonstrates low-intensity intrasellar signal representing cerebrospinal fluid (CSF; compare with signal within the fourth ventricle). **B:** Axial T2-weighted MR scan on a different patient shows increased signal within the sella representing CSF on this pulse sequence (compare with signal from incidentally noted anterior temporal arachnoid cysts). (Courtesy of Drs. J.A. Bello and S.K. Hilal.)

TREATMENT

Treatment of pituitary adenomas begins with the correction of electrolyte dysfunction and replacement of pituitary hormones, if necessary, immediately after diagnostic blood specimens have been sent. Replacement of thyroid or adrenal hormones is of particular importance. Steroid replacement must be adequate for stressful situations, including the perioperative period.

The goals of treatment differ according to the functional activity of the tumor. For endocrinologically active tumors, an aggressive approach toward reversing hypersecretion is essential while preserving normal pituitary function. This can usually be achieved by surgical excision, although prolactinomas are better controlled medically by giving dopamine agonists that achieve tumor shrinkage in 75% to 80% of patients ([Fig. 58.6](#)). Candidates for surgical treatment include patients with prolactinomas that fail to respond medically or those who cannot tolerate the side effects of medication. The treatment strategies for secretory adenomas are covered in detail in [Chapter 146](#).

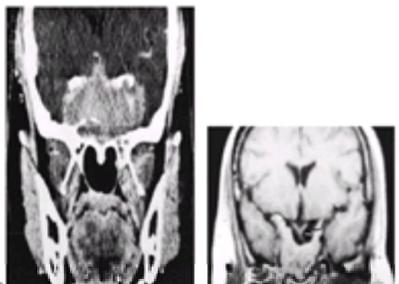

FIG. 58.6. **A:** Coronal computed tomography with contrast from a 40-year-old man with bitemporal hemianopsia and a markedly elevated serum prolactin level. A large pituitary adenoma with suprasellar and parasellar extension can be easily seen. **B:** Coronal magnetic resonance scan with contrast after bromocriptine therapy shows marked decrease in the tumor size such that the infundibulum and optic chiasm are decompressed (*arrow*).

Nonsecreting tumors are best treated by surgical reduction of the mass but maintaining pituitary function. Although complete surgical resection is desired, the radiosensitivity of these tumors invites subtotal debulking followed by radiation therapy to reduce the risk of recurrence or progression.

Incidentally discovered asymptomatic adenomas require no intervention but should be followed with periodic visual field examination and MRI. Onset of symptoms or MRI documentation of growth are indications for treatment.

Surgery

The efficacy and safety of the transsphenoidal approach make it the procedure of choice for the removal of adenomas. Most tumors are soft and friable; transsphenoidal access, although limited, permits complete removal even if there is suprasellar extension or the sella is not enlarged. Transsphenoidal surgery was originally developed by Cushing and popularized by others, especially Hardy (1971). Refinements in microsurgery and the availability of steroid replacement and antibiotics have dramatically improved the results. Mortality rates are less than 1%. Major morbidity is less than 3.5%, including stroke, visual loss, meningitis, CSF leak, or cranial nerve palsy. Permanent diabetes insipidus appears after surgery in 25% of patients and is treated by replacement.

A transcranial approach may be preferred for tumors extending into the middle fossa or if there is suprasellar growth through an intact diaphragm sella, with a waistband constriction of the tumor ([Fig. 58.7](#)). A transcranial approach may be necessary to decompress the optic structures before radiation when a transsphenoidal

approach fails to adequately debulk the tumor and there is persistent major visual loss.

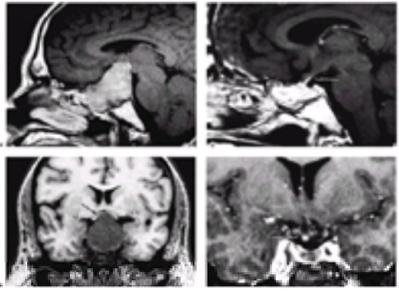

FIG. 58.7. **A:** Sagittal magnetic resonance (MR) scan showing a large pituitary adenoma filling the sphenoid sinus and extending into the floor of the third ventricle. **B:** On the coronal view, the suprasellar component can be seen compressing the optic chiasm (*arrow*). A large tumor such as this often requires a craniotomy to decompress the optic structures adequately. **C:** Sagittal MR scan after a gross total resection of the pituitary adenoma through an extended frontal craniotomy. There are postoperative changes in the sella and sphenoid sinus, and the infundibulum is well decompressed (*arrow*). **D:** On the coronal view, there is no residual tumor, and the optic chiasm and a portion of the infundibulum can be clearly seen (*arrow*).

Radiation Therapy

Radiation therapy is complementary to surgery in preventing progression or recurrence. Standard radiation uses three fields (parallel opposed fields with a coronal field) or rotational techniques to avoid unnecessary dosage of the temporal lobes. Dosages of 4,500 to 5,000 cGy delivered in 180-cGy fractions are recommended. Radiation may be the only treatment for patients who are poor operative risks, but histologic confirmation is generally desired. Radiation therapy is usually not the initial treatment for hormonally active tumors because it rarely lowers hormone levels to normal and then only after a delay of months or years.

In general, patients with subtotally resected tumors are given radiation therapy. Although radiation reduces the risk of recurrence or delays recurrence of gross total resection, we follow these patients with serial MR images and visual field examination and withhold radiation unless there is documented tumor regrowth.

Early complications of radiation therapy are transient and involve minor inconvenience such as epilation, dry mouth, and altered taste or smell. The most common and important delayed complication is hypopituitarism, which may occur any time from 6 months to 10 years after treatment. Some degree of hypopituitarism occurs in 30% to 50% of patients. Annual endocrine evaluation is necessary to treat this appropriately. Other rare complications include visual loss, radiation necrosis of the temporal lobes, and radiation-induced tumors. To minimize risk of visual loss, optic structures should be decompressed before radiation therapy.

New techniques such as focused beam therapy with proton beams, gamma knife, or linear accelerator are being investigated. In these methods, a single high-dose fraction is directed to a limited volume, giving a biologic effect that differs from fractionated radiotherapy. Although these methods may produce adequate tumor control, there is concern about damage to critical structures in the optic chiasm or even cranial nerves; there may be a higher incidence of hypopituitarism. Intracapsular implantation of radioactive isotopes is also being evaluated.

Recurrent Tumors

Patients with recurrent tumors are management challenges. Treatment must be individualized. If the patient has not had prior radiation, then radiation would be the treatment of choice. Otherwise, repeat transsphenoidal surgery is usually indicated. Other treatment options include additional salvage radiation or some form of stereotactic radiation.

[Suggested Readings](#)

EPIDEMIOLOGY

Malignant and benign tumors of the central nervous system (CNS) may occur at any time in infancy and childhood. Astrocytomas are the largest group, mostly of low-grade histology. Next are medulloblastomas, the most frequent malignant tumor. After these are congenital and acquired lesions, a diverse group that includes craniopharyngiomas, ependymomas, choroid plexus tumors, teratomas, and other germ cell tumors. Apart from occasional high-grade astrocytomas, the usual tumors of adults (glioblastoma multiforme, anaplastic astrocytoma, meningioma, oligodendroglioma, pituitary adenoma) are rarely seen. CNS metastases from solid tumors are also uncommon in children compared with adults.

Primary CNS tumors account for 20% of all childhood cancers, second only to leukemia. Approximately 2,200 cases are diagnosed annually in the United States in children under age 15 years, an incidence of 2.8 per 100,000. The reported incidence of childhood brain tumors in the United States increased by 35% between 1973 and 1994, due mainly to increased numbers of supratentorial low-grade gliomas and brainstem tumors diagnosed annually starting in the mid-1980s. This is probably related to the introduction and rapid dissemination of magnetic resonance imaging (MRI) at that time and the fact that MRI is considerably more sensitive than computed tomography (CT) for detection of focal low-grade tumors of the cerebrum and brainstem.

The causes of congenital and childhood CNS tumors remain unknown. There is a slight male preponderance. Most CNS tumors are sporadic, but some are seen in association with inherited genetic disorders. Children with neurocutaneous syndromes are at increased risk. For example, individuals with *neurofibromatosis type 1* (NF-1) have a 10% chance of developing an intracranial tumor, and in childhood these may include optic pathway gliomas and astrocytomas elsewhere in the brain and spinal cord. The *NF1* gene maps to chromosome 17q11.2, so it is of interest that allelic loss on chromosome 17q occurs in one-fourth of pilocytic astrocytomas, suggesting the presence of a tumor suppressor gene. In the less common *neurofibromatosis type 2*, there is a predisposition to bilateral vestibular schwannomas, which exhibit chromosome 22q deletion and *NF2* gene mutations in at least half of cases. *NF2* also predisposes to ependymomas, which commonly show chromosome 22q deletion, but analysis of the *NF2* gene in ependymomas has revealed only a single mutation in a tumor that had lost the remaining wild-type allele.

Children with *tuberous sclerosis* may develop subependymal giant cell astrocytoma or occasionally ependymoma. Linkage studies have identified tuberous sclerosis genes on chromosomes 9q and 16p; allelic loss of 9q and 16p loci has been demonstrated in some subependymal giant cell astrocytomas, suggesting a tumor suppressor function. In the *epidermal nevus syndrome*, there is an increased risk of astrocytomas and primitive neuroectodermal tumors (PNETs). Hemangioblastomas of the cerebellum, medulla, and spinal cord are associated with *von Hippel-Lindau disease*, and choroid plexus tumors have occasionally been reported. Loss of chromosome 3p sequences has been described in one choroid plexus tumor, suggesting involvement of the VHL gene.

Combined cytogenetic and molecular studies of the common sporadic childhood brain tumors have identified certain genomic alterations that may also lead to the identification of genes contributing to tumorigenesis. For example, isochromosome 17q is found in approximately half of medulloblastomas (PNETs), suggesting the presence of a tumor suppressor gene.

Environmental risk factors for the development of CNS tumors include exposure to ionizing radiation. In children treated for acute lymphoblastic leukemia, there was a 1.39% cumulative incidence of secondary brain tumors (gliomas and meningiomas) at 20 years, and cranial irradiation was a dose-dependent predisposing factor. There is inconclusive evidence for any risk associated with electromagnetic fields (from electric blankets or other residential exposure). Several studies have shown an association between farm and animal exposures and childhood brain tumors, but dietary exposure to *N*-nitroso compounds, implicated in animal studies of brain tumor causation, was not a risk factor in young children. Maternal intake of folic acid in pregnancy may be protective against the development of PNETs, and a study in England found that the incidence of medulloblastoma declined after 1984, when multivitamin supplementation in pregnancy became widespread after reports that multivitamins with folate reduced the risk of neural tube defects.

SYMPTOMS

Children with brain tumors most often present with symptoms and signs of increased intracranial pressure. This results from obstruction of normal cerebrospinal fluid (CSF) pathways, leading to ventriculomegaly, and secondarily from direct mass effect of bulky tumors. Characteristic signs are headache, vomiting, and diplopia, but the onset may be gradual and nonfocal. Fatigue, personality change, or worsening school performance may be described. Symptoms in infants are particularly nonspecific and may include irritability, anorexia, persistent vomiting, and developmental delay or regression, with macrocephaly and seemingly forced downward deviation of the eyes ("sunsetting sign"). Persistent vomiting, recurrent headache (awakening the child from sleep), neurologic findings (ataxia, head tilt, vision loss, papilledema), endocrine disturbance (growth deceleration, diabetes insipidus), and stigmata of neurofibromatosis should all prompt further evaluation for the presence of a CNS tumor.

Symptoms and signs reflect tumor location, and in children (unlike adults), CNS tumors are divided about equally between supratentorial and infratentorial sites ([Table 59.1](#)). *Supratentorial tumors*, which predominate in infants and toddlers and also occur in older children, cause headache, motor weakness, sensory loss, and occasionally seizures, deteriorating school performance, or personality change. Frontal lobe tumors affect personality and movement. Temporal lobe tumors may cause partial complex seizures or fluent aphasias. The incidence of underlying neoplasm in children with intractable epilepsy approaches 20%, and the increased risk of having a brain tumor is noted even 10 or more years after a diagnosis of epilepsy. Parietal lobe tumors affect reading ability and awareness of contralateral extremities (hemineglect). Occipital lobe tumors cause visual field disturbance and occasionally hallucinations. Suprasellar lesions may cause both visual field defects and endocrine dysfunction. Parinaud syndrome (upgaze paresis and mild pupil dilatation with better reaction to accommodation than light, retraction or convergence nystagmus, and lid retraction) is specifically found in patients with pineal region tumors.

TABLE 59.1. LOCATION OF CENTRAL NERVOUS SYSTEMS TUMORS IN INFANTS, CHILDREN, AND ADOLESCENTS

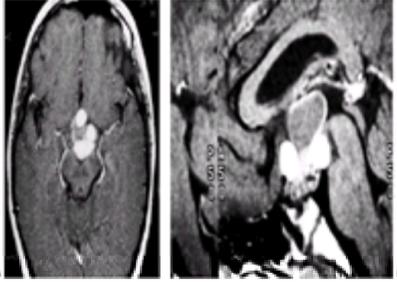

FIG. 59.1. Axial (A) and sagittal (B) magnetic resonance images of a craniopharyngioma.

Epidermoids (cholesteatomas) are the most common embryonal CNS tumors and account for about 2% of all intracranial tumors. They arise within skull tables or adjacent to the dura, usually in the suprasellar region, skull base, brainstem or cerebellopontine angle, or within a ventricle. They are encapsulated, have a pearly appearance, and may contain cyst fluid with cholesterol crystals. Clinical onset is usually in young adulthood, with variable rate of progression depending on location. MRI demonstrates a lesion with low T1-weighted signal intensity and high T2-weighted signal intensity ([Fig. 59.2](#)). Diffusion imaging can be helpful. Treatment is surgical resection.

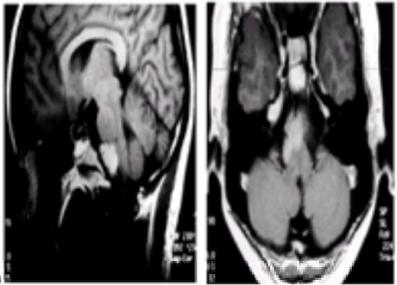

FIG. 59.2. Sagittal (A) and axial (B) magnetic resonance images of a pontomedullary epidermoid.

Dermoid tumors are also cystic, and sebaceous gland secretions impart a dark yellow color to the cyst fluid. Intracranial dermoids are associated with Goldenhar syndrome (oculo-auriculo-vertebral dysplasia). Treatment is surgical resection.

Teratomas occur in infants and young children. Prenatal diagnosis of an intracranial teratoma has been reported. Mature teratomas are generally lobulated and cystic, often containing differentiated tissues such as bone, cartilage, teeth, hair, or intestine. Immature and malignant teratomas are less common. Teratomas tend to occur in the pineal region, presenting with Parinaud syndrome and hydrocephalus. They comprise about 4% of childhood intracranial tumors and also occur in the spine. Treatment is surgical resection.

Chordomas develop from remnants of the embryonic notochord. Half are in the sacrococcygeal region, one-third at the sphenoid-occipital junction, and the remainder elsewhere along the spinal column. They are rare, accounting for less than 1% of CNS tumors, and usually remain asymptomatic until adulthood. These tumors are locally invasive and cause vision loss or cranial nerve dysfunction. They can invade the nasopharynx or intracranial sinuses and may extend into the neck, causing torticollis. Chordomas have a smooth nodular surface that resembles cartilage; the characteristic histologic feature is the presence of large masses of physaliferous cells, round or polygonal cells arranged in cords and having large cytoplasmic vacuoles containing mucin. Chordomas grow slowly but may recur after excision. A chondroid variant contains prominent cartilage. A malignant variant is distinguished by mitotic spindle cells and may metastasize to the lung. Chordoma should be suspected in a patient presenting with multiple cranial nerve palsies or erosion of the skull base. Treatment is surgical resection, occasionally with postoperative irradiation.

Choroid plexus tumors are rare congenital tumors found in or near a lateral ventricle. They may cause symptoms shortly after birth, and most are diagnosed before age 2 years. About two-thirds are benign papillomas, and the remainder are carcinomas. The first manifestation is likely to be macrocephaly due to hydrocephalus, with bulging fontanelle and split sutures noted in infants. Excess CSF production due to tumor may approach 2,000 mL/day. Papillomas usually grow into the ventricle and tend not to be invasive. Carcinomas typically invade the parenchyma and cause hydrocephalus ([Fig. 59.3](#)). Surgical resection is curative and stops the excessive production of CSF. Carcinomas are invasive and nearly half disseminate in the CSF. Total excision of localized lesions can be curative, whereas cisplatin-based chemotherapy appears to be effective in patients with residual tumor.

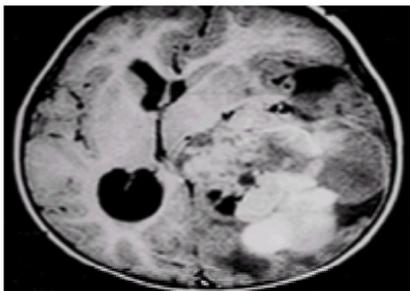

FIG. 59.3. Magnetic resonance image of a choroid plexus carcinoma of the lateral ventricle, with parenchymal invasion.

Colloid cysts of the third ventricle presumably arise from the anlage of the paraphysis. These lesions grow in the anterior superior portion of the third ventricle as small white cysts filled with homogeneous gelatinous material. They do not usually cause symptoms until adulthood, when there may be intermittent hydrocephalus. Disturbance of the limbic system may cause emotional and behavioral changes in some instances. Treatment is surgical excision.

ASTROCYTOMAS

Cerebellar astrocytomas constitute approximately 12% of childhood brain tumors and 30% to 40% of posterior fossa tumors. The peak incidence is early in the second decade. These tumors arise most often in the lateral cerebellar hemispheres rather than in the vermis. Symptoms of clumsiness and unsteadiness may be present for months and eventually are accompanied by intermittent morning headache and vomiting. Midline lesions have a shorter symptom interval. Truncal ataxia, dysmetria, and papilledema are usually present at diagnosis. Head tilt may be present, but other cranial nerve palsies or long tract signs are infrequent and suggest brainstem invasion. Cerebellar astrocytomas may be primarily cystic or solid, and cystic lesions may have a nodule ([Fig. 59.4](#)). Most are histologically benign. The typical

juvenile pilocytic astrocytoma contains areas of compact fibrillated cells with microcysts and eosinophilic structures called Rosenthal fibers. These lesions have greater than 90% survival with surgery alone. The tumor and associated cyst should be removed completely. If there is residual tumor, re-resection should be considered; focal radiotherapy may be offered if there is disease progression. Some patients have infiltrating tumors with hypercellularity or frank anaplasia; these have been considered diffuse or anaplastic astrocytomas, are harder to resect because of brainstem invasion, and have approximately 30% recurrence-free survival. Local radiotherapy does not appear to improve survival, and the value of craniospinal irradiation or chemotherapy is unclear.

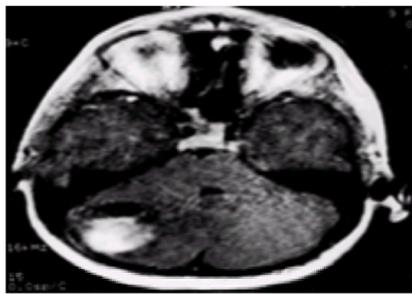

FIG. 59.4. Magnetic resonance image showing lateral location of a partly cystic, partly solid cerebellar astrocytoma.

Brainstem gliomas carry the worst prognosis of any childhood brain tumor. Brainstem tumors constitute 10% to 20% of posterior fossa tumors, with a peak age of 5 to 8 years. Most arise in the pons, and there may be contiguous spread to the medulla or midbrain. Despite the clinical aggressiveness of these tumors, the histologic appearance at initial diagnosis is quite variable, but at autopsy a substantial portion shows anaplastic features. This may reflect sampling error at initial biopsy or subsequent malignant transformation. These tumors infiltrate the brainstem and compress normal structures, while extending superiorly and inferiorly to produce diffuse enlargement of the brainstem. Diffuse intrinsic pontine lesions are nearly uniformly fatal within 18 to 24 months. Some tumors extend ventrally, laterally, or posteriorly, and the primarily exophytic tumors tend to be more accessible to surgical resection and carry a better prognosis, as do focal midbrain lesions.

The course is insidious, with slowly progressive cranial neuropathy, motor symptoms, and disturbance of gait, swallowing, and speech. Vomiting and headache indicate the presence of hydrocephalus, generally a late finding. Children with dorsal exophytic lesions may have more unsteadiness and less evidence of cranial nerve dysfunction. CT shows a low-density lesion in the brainstem with compression and obliteration of surrounding cisterns but little if any contrast enhancement. Uncommonly, brainstem tumors may be isodense or hyperdense with cystic areas. MRI is preferred because of the detail appreciated on sagittal images, typically revealing more extensive disease than appreciated on CT. The MR appearance is of decreased signal intensity on T1-weighted images ([Fig. 59.5A](#)) and increased T2-weighted signal. MRI may also demonstrate infiltration of the medulla ([Fig. 59.5B](#)) or thalamus.

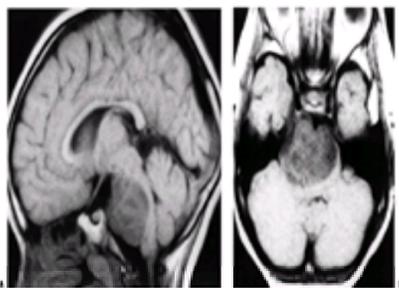

FIG. 59.5. A: Sagittal magnetic resonance image of a diffuse brainstem glioma. **B:** Axial image showing infiltration of the medulla.

Given the accuracy of MR diagnosis, the morbidity of surgery, and the variable prognostic impact of biopsy, it has been accepted that surgery is not warranted for the 70% of patients with diffuse intrinsic pontine lesions, in whom major resection when attempted has not improved survival. Patients with exophytic cervicomedullary tumors are more likely to benefit from surgery, as are patients with atypical clinical course or MR findings (symptom duration exceeding 6 months, absence of cranial nerve findings, primarily exophytic or focal ring-enhancing lesions). Standard treatment has involved field radiation therapy, except in the case of completely resected focal lesions. Most children with brainstem gliomas benefit at least transiently from radiation therapy to a dose of 54 to 56 Gy. Hyperfractionated irradiation to a dose of 72 to 78 Gy in smaller twice-daily fractions did not alter survival for patients with diffuse pontine lesions, nor did accelerated radiotherapy in standard fractions given twice daily. Although leptomeningeal dissemination can occur, the main risk is for local recurrence. Chemotherapy and immunotherapy have been unsuccessful in this condition, although new agents continue to be studied.

Diencephalic and optic pathway gliomas constitute up to 5% of childhood CNS tumors. Unilateral optic nerve tumors are generally diagnosed in the first decade of life, and optic chiasm tumors tend to present either in infancy or the second decade. An association with NF-1 is present in 50% to 70% of patients with isolated optic nerve tumors and 10% to 20% of patients with optic chiasm tumors. Adolescents are more likely to complain of slowly progressive vision loss. Infants are more likely to be evaluated because of strabismus, nystagmus, or developmental delay. Patients with contiguous optic nerve involvement usually present with proptosis and optic pallor or atrophy. Intraorbital lesions usually cause decrease in central vision, whereas chiasmatic tumors produce bitemporal hemianoptic field deficits. Nystagmus may be present in the more involved eye, and amblyopia is common. With routine MRI of NF-1 patients, lesions may be detected before onset of any symptoms. There may be associated endocrine disturbances such as growth deceleration, precocious puberty, and diencephalic emaciation. Thalamic lesions present with hemiparesis or hemisensory loss. Hypothalamic tumors have insidious onset and may be associated with altered mental status, endocrine dysfunction, and focal neurologic deficits.

CT or MRI appearance of diencephalic gliomas is of hypo- or isodense lesions with variable contrast enhancement. Larger lesions may be cystic ([Fig. 59.6](#), [Fig. 59.6A](#) and [Fig. 59.6B](#)). Visual pathway tumors may be confined to the optic chiasm ([Fig. 59.7](#), [Fig. 59.7A](#) and [Fig. 59.7B](#)) or may show abnormal enhancement along the optic tracts and radiations. This streaking phenomenon is best appreciated on MRI, particularly with FLAIR sequence. Most diencephalic tumors are low-grade fibrillary or pilocytic astrocytomas. The natural history of these lesions is unpredictable. Visual pathway tumors have a particular tendency to spread to contiguous structures. The role of surgery is unclear. In patients with diffusely infiltrating lesions, especially with NF-1, diagnosis may be confirmed with near certainty on neuroimaging alone, and surgery may be deemed of little benefit. In patients with unilateral blindness, surgery may be recommended for treatment of a severely proptotic eye. However, if some vision persists, local radiotherapy may be recommended. Radiotherapy at doses of 45 to 55 Gy generally reverses tumor progression in nearly all patients and stabilizes or improves vision in most. There may be apparent tumor enlargement at 6 to 12 weeks as a transient effect of the radiation. Patients with very large lesions may benefit from preliminary surgical debulking. The major disadvantage of radiotherapy is potential adverse endocrine and neurocognitive effects, especially in younger children. Chemotherapy (vincristine and carboplatin) has been beneficial as initial treatment in children under 5 years of age with progressive optic pathway and hypothalamic/chiasmatic gliomas, delaying the need for radiotherapy by a median of 4 years; most eventually relapse, however, except for NF-1 patients who tend to have indolent disease. The same chemotherapy regimen has been advocated as initial treatment for infants with tumor-associated diencephalic syndrome of emaciation.

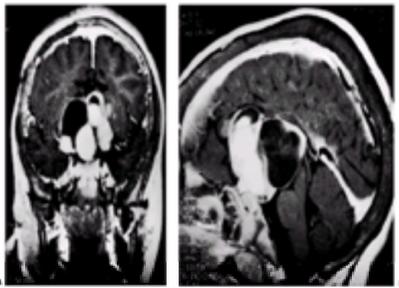

FIG. 59.6. Coronal (A) and sagittal (B) magnetic resonance images of a large hypothalamic glioma.

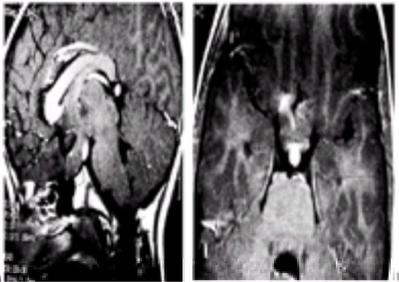

FIG. 59.7. Sagittal (A) and coronal (B) magnetic resonance images of an optic pathway tumor.

Cerebral hemispheric low-grade gliomas appear with a peak incidence between ages 2 and 4 years and again in early adolescence. In toddlers there may be symptoms of increased intracranial pressure, developmental delay, and growth retardation and specific signs such as weakness, sensory loss, or vision deficit. These slow-growing pediatric tumors are far less likely than adult gliomas to undergo malignant degeneration. They are infiltrating, however, and may cause seizures, either generalized or focal, the latter particularly suggestive of an occult brain tumor such as a ganglioglioma. CT most often reveals a relatively homogeneous low-density variably enhancing lesion with indistinct margins. MRI is more sensitive, showing decreased T1-weighted signal and increased T2-weighted signal and providing better resolution of tumor and peritumoral edema. Gross total resection often affords long-term disease control but may not be curative. Radiation therapy at doses of 50 to 55 Gy is commonly given postoperatively, at least in older children with less than radical resection, and 5-year survival rates are 75% to 85%. For younger children with residual or recurrent tumor, chemotherapy (vincristine and carboplatin) has been used in an attempt to defer radiotherapy, and prospective trials evaluating this approach are in progress.

Cerebral hemispheric high-grade astrocytomas account for about 11% of childhood brain tumors. High-grade astrocytomas can be classified according to cytologic appearance (as fibrillary, pilocytic, gemistocytic, xanthomatous, or protoplasmic) and by degree of anaplasia. Kernohan's classification grades astrocytomas on a scale of 1 to 4, with grade 3 (*anaplastic astrocytoma*) and grade 4 (*glioblastoma multiforme*) representing high-grade lesions. The World Health Organization classification emphasizes degree of cellularity, nuclear and cellular pleomorphism, mitosis, endothelial proliferation, and necrosis and identifies three gradations: astrocytomas, anaplastic astrocytomas, and glioblastoma multiforme. In general, anaplastic astrocytomas are composed of astrocytes with increased cellularity, pleomorphism, and numbers of mitoses. There may be focal necrosis, but not so extensive as to form pseudopalisades. Glioblastoma multiforme has prominent vascular proliferation and a pseudopalisading pattern of necrosis. Cytogenetic analyses (mainly of tumors from adults) has shown consistent chromosomal abnormalities in all tumor grades, but one aberration, the loss of part or all of chromosome 10, has been specifically associated with glioblastoma multiforme, and amplification and rearrangement of the epidermal growth factor receptor gene have also been associated with malignant histology.

Common symptoms include headache, vomiting, seizures, motor weakness, and behavioral abnormalities. Symptom duration is generally less than 3 months. Diagnosis is best made by contrast-enhanced CT or preferably MRI. Surgery is important for establishing a diagnosis and removing tumor, and major resection is associated with improved survival. However, because these are infiltrative tumors that may also disseminate in the CSF, they will almost certainly recur without further therapy. Postoperative involved field irradiation (59 to 60 Gy) and adjuvant chemotherapy both increase survival. Adjuvant vincristine plus lomustine was effective in a prospective randomized trial, but survival in recent studies remains below 35%. Survival is clearly influenced by extent of tumor resection, and there may be a benefit of consolidative high-dose chemotherapy with hematopoietic stem cell rescue in patients rendered free of detectable tumor after surgery and radiotherapy, based on experience with this approach in patients with recurrent high-grade astrocytomas.

Spinal cord astrocytomas are rare, accounting for only about 4% of childhood CNS neoplasms. They may occur in any part of the cord, with the solid component extending an average of five spinal segments and additional cystic component within or at either end of the lesion. Most have benign histologic appearance and grow slowly. Symptoms and signs may include pain (either localized or radicular), weakness or spasticity, gait disturbance, and bowel or bladder dysfunction. Gadolinium-enhanced MRI is the preferred modality for demonstrating the location of the solid tumor, associated cyst, and edema. Intramedullary tumors may be missed altogether on myelography unless CT is done. Treatment may be attempted gross total or near total resection or partial resection with decompression of cysts and postoperative radiotherapy. The degree of neurologic recovery depends on the preoperative condition of the patient. A potential complication is spinal deformity, due to laminectomy, radiotherapy, or both. For children with low-grade tumors, survival rates of 55% at 10 years have been reported after partial resection and radiotherapy. Chemotherapy has been substituted for radiotherapy in very young children. The prognosis for children with high-grade tumors is worse, although 5-year progression-free survival of 46% was reported in a study using combined radiation therapy and chemotherapy.

MEDULLOBLASTOMAS/PRIMITIVE NEUROECTODERMAL TUMORS

Medulloblastoma and related PNETs outside the posterior fossa collectively represent the most common malignant CNS tumors of childhood. The presumed cell of origin is derived from remnants of fetal external granular cells of the cerebellum or rests in the posterior medullary velum. Most PNETs arise in the posterior fossa and are specifically called medulloblastomas. These tumors account for about 30% of infratentorial tumors in children but are extremely uncommon in adults. Medulloblastomas typically involve the cerebellar vermis and grow to fill the fourth ventricle and infiltrate the floor of the ventricle and adjacent structures. The tumor may arise more laterally, especially in older patients. The histologic appearance is of a small round cell tumor with glial or other types of differentiation in some cases. There may be staining for both neurofilament protein and glial fibrillary acidic protein but also for synaptophysin, which is more specific for PNET. In infants, medulloblastoma must be distinguished from the atypical teratoid/rhabdoid tumor, which has a small cell component resembling medulloblastoma but also cords of cells in a mucinous background (simulating chordoma), with "rhabdoid" appearance of the cytoplasm of the larger cells.

A specific chromosome abnormality, isochromosome 17q (duplication of the long arm or deletion of the short arm of chromosome 17), may be seen in one-third of cases. This could result in inactivation of a tumor suppressor gene located on chromosome 17 but apparently distinct from p53. It is unclear whether chromosome 17p deletions impart poor prognosis, but analysis of DNA content indicates that diploid tumors have worse outcome than aneuploid or hyperdiploid tumors. Relatively less is known about the cytogenetic and molecular features of supratentorial PNETs. An animal model of medulloblastoma has been produced by intracisternal injection of human medulloblastoma cells into nude rats.

Children with medulloblastoma typically present with symptoms of increased intracranial pressure (vomiting, lethargy, morning headache), unsteadiness, and diplopia. The median age is 5 years. Symptom duration is generally less than 3 months. There may be recent onset of head tilt due to ophthalmoparesis or incipient cerebellar herniation. Laterally situated lesions present slightly differently, with symptoms of cerebellopontine angle disturbance or appendicular ataxia. These tumors appear isodense or hyperdense on noncontrast CT and usually enhance homogeneously with contrast. Evidence of hydrocephalus is present in more than 80% of patients.

Other features on CT may include small cysts, calcification, and hemorrhage. MRI may give a better indication of tumor extent ([Fig. 59.8A](#)) and possible leptomeningeal dissemination ([Fig. 59.8B](#) and [Fig. 59.8C](#)). MRI is also the preferred study for evaluation of the spine for disseminated tumor, which may be present in up to one-third of patients.

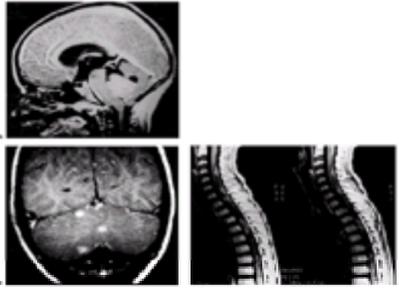

FIG. 59.8. (A) Sagittal magnetic resonance image of a medulloblastoma in the posterior fossa, with (B) coronal image showing parenchymal nodules and (C) spine images showing seeding of the cord.

Modern neurosurgical techniques permit complete or near complete resection of medulloblastomas in most cases, limited mainly by infiltration of the fourth ventricle, the brainstem, or one of the cerebellar peduncles. Neurologic morbidity may include the “posterior fossa syndrome” of aseptic meningitis or, less commonly, mutism, pharyngeal dysfunction, and ataxia. Preoperative ventriculoperitoneal shunting is not done routinely because of the risk of upward herniation and because hydrocephalus will be relieved by tumor removal in most patients. About 30% to 40% will require permanent shunting. Postoperative CT or MRI is indicated to confirm the extent of resection, and this study should be done within 72 hours when there is less edema than later. The overall 5-year disease-free survival is approximately 50%. Children with completely resected localized tumors have up to 70% disease-free survival. The presence of residual tumor (more than 1.5 cm³), brainstem invasion, or leptomeningeal spread portends a worse prognosis. It has also been suggested that boys may have an inferior outcome. Radiation therapy is the standard postoperative treatment for this disease, and craniospinal irradiation is given because the entire neuraxis is at risk for recurrence. Conventional doses are 36 Gy to the brain and spine, with an 18- to 20-Gy boost to the local tumor site.

Adjuvant chemotherapy with vincristine and lomustine has been shown to improve survival in advanced stages of medulloblastoma, and with the addition of cisplatin progression-free survival of 85% at 5 years has been reported. This result suggests that chemotherapy could improve results even in patients with localized tumors, who are conventionally treated with radiation therapy alone. Chemotherapy can potentially allow for reduction in the dose of radiation to the brain and spine in such patients, and this approach is currently under study. Chemotherapy has also been used as primary postoperative treatment in infants, with the goal of deferring or avoiding radiotherapy. Current protocols for infants up to age 3 years use this approach, with increasingly intensive regimens to enhance the response rate to chemotherapy and improve the control of leptomeningeal disease. Finally, high-dose chemotherapy with hematopoietic stem cell rescue is an effective salvage therapy for selected patients with recurrent medulloblastoma.

Supratentorial PNETs are histologically equivalent to medulloblastoma and treated with the same approach of resection, craniospinal irradiation, and chemotherapy. Prognosis is also similar, about 50% survival at 5 years. Pineal region PNETs (pineoblastomas) must be distinguished from pineal germ cell tumors (see below) and pineocytomas, which are considered benign and treated by surgery with or without radiotherapy. Pineoblastomas are treated like medulloblastoma, with craniospinal irradiation and adjuvant chemotherapy, and 60% 3-year progression-free survival has been reported.

EPENDYMOMAS

Ependymomas usually arise within or adjacent to the ependymal lining of the ventricular system, with 60% to 75% in the posterior fossa. They constitute 5% to 10% of all primary childhood brain tumors. Ependymomas are glial neoplasms derived from ependymal cells, and most appear to be histologically mature. Variants include anaplastic ependymoma, which may or may not have a worse outcome, and subependymoma, a lower grade lesion in which the fibrillary subependymal astrocyte predominates. Ependymoblastoma, a primitive tumor, is better categorized as a type of PNET. Simian virus 40-related DNA sequences have been demonstrated in ependymomas and choroid plexus carcinomas, suggesting a potential viral etiology. Cytogenetic and molecular studies of childhood ependymomas have revealed rearrangements or deletions of chromosome 6 and of chromosomes 22 and 17.

Clinical symptoms depend on tumor location. Children with ependymoma filling or compressing the fourth ventricle present with nausea, vomiting, and morning headache due to obstructive hydrocephalus. Tumors arising low in the fourth ventricle and extending into the lower medulla may cause neck pain, whereas cranial nerve palsies may result from brainstem invasion or compression of cranial nerves. In patients with supratentorial lesions, seizures and focal deficits are seen. Features on CT include calcification and variable enhancement. MRI may better demonstrate invasion of posterior fossa lesions into the brainstem ([Fig. 59.9](#)) or upper cervical spinal cord. The most important predictor of outcome is the extent of surgical resection. In posterior fossa lesions, this can be limited by infiltration of the brainstem, extension into the cerebellar pontine angle, or involvement of cranial nerve nuclei. Supratentorial lesions may also be quite infiltrative and difficult to remove. Total resection of ependymomas affords 60% or greater survival at 5 years, whereas two-thirds recur after subtotal resection. Postoperative imaging has been considered more accurate than surgeons’ estimate of presence of residual tumor.

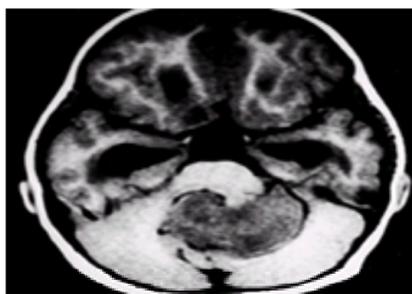

FIG. 59.9. Magnetic resonance appearance of an ependymoma, showing tumor extension through the foramen of Luschka and invasion of the brainstem.

Postoperative radiation therapy seems to increase overall survival, and treatment to an involved field (at a dose of 55 Gy) is generally considered sufficient because relapses are overwhelmingly local. The need for larger volumes of radiation therapy to anaplastic lesions or presymptomatic irradiation to the neuraxis for posterior fossa lesions is not definitely established. Adjuvant chemotherapy may improve outcome, based on response of recurrent ependymoma to cisplatin and other agents, and preirradiation chemotherapy is being evaluated in patients with postoperative residual tumor based on responses seen in infants with ependymoma. Recurrent ependymomas are managed by re-resection and chemotherapy or stereotactic radiosurgery.

GERM CELL TUMORS

Germ cell tumors tend to arise in the pineal and suprasellar regions. They account for about half of pineal tumors and 5% to 10% of parasellar lesions. Pineal germ cell tumors have a male preponderance and usually present in adolescence, whereas suprasellar germ cell tumors predominate in younger females. About 50% to 65% of germ cell tumors are germinomas, histologically primitive lesions resembling gonadal germ cell tumors and presumably derived from embryonic migration of

totipotent germ cells. Teratomas and mixed germ cell tumors are variously comprised of mature, immature, and malignant elements. Choriocarcinomas are rare but highly malignant.

Symptoms and signs of pineal region germ cell tumors most often include headache and Parinaud syndrome of upgaze paresis. With extension to the overlying thalamus there may be hemiparesis, incoordination, vision disturbance, or movement disorder. Suprasellar germ cell tumors produce pituitary and hypothalamic dysfunction but usually not vision loss. CT appearance is of an irregular lesion of mixed density, occasionally with calcification and with variable contrast enhancement. MRI may be preferred as it is more sensitive for purposes of follow-up evaluation. Because of its sensitivity, MRI may reveal the presence of a pineal cyst in otherwise healthy children being evaluated for headache; lack of hydrocephalus and Parinaud syndrome should lead one away from the diagnosis of a pineal tumor. Diagnosis can be aided by measurement of alpha-fetoprotein and beta subunit of human chorionic gonadotropin, which are secreted by germ cell tumors (but not pineal parenchymal cell tumors or cysts) and detectable in serum and CSF. Alpha-fetoprotein is elevated in endodermal sinus tumors and some immature teratomas; human chorionic gonadotropin is elevated in choriocarcinoma and embryonal carcinomas. Elevation of both indicates the presence of mixed malignant elements. Even with marker elevation, however, histologic confirmation is recommended.

Surgery for pineal region tumors is technically difficult, but major resections can be achieved with acceptable morbidity by a supratentorial suboccipital or infratentorial supracerebellar approach. There may be transient visual migraine due to occipital lobe contusion. Teratomas may be encapsulated and easier to remove. Germ cell tumors may disseminate throughout the neuraxis in up to 10% of cases. Radiotherapy is the standard treatment for pure germinomas, typically 35 to 45 Gy to the brain and spine with a 10- to 15-Gy boost to the area of the tumor, affording 90% survival at 5 years. Survival rates for mixed malignant germ cell tumors are considerably lower, less than 30% with radiotherapy alone, but about 50% with the addition of chemotherapy. Current protocols are based on cisplatin-containing regimens active in gonadal germ cell tumors.

LYMPHOMAS

Primary CNS lymphomas are rare, constituting less than 1% of intracranial tumors. They may occur at any age. They are generally of B-lymphocyte origin, including Burkitt type. They are associated with congenital and acquired immunodeficiency, including immunosuppressive therapy for autoimmune disease and organ transplant. The incidence has increased in both immunodeficient and immunocompetent individuals. The most common location is the cerebral cortex. CT appearance is of an isodense or hyperdense lesion with moderate to marked contrast enhancement. MRI shows an iso- to hypointense lesion on T1-weighted images and iso-, hypo-, or slightly hyperintense lesion on T2-weighted images, with variable gadolinium enhancement. Survival rates in adults of 20% to 30% have been reported with combined radiation and chemotherapy or intensive chemotherapy alone.

MENINGIOMAS

Meningiomas are rare in childhood. There is an association with neurofibromatosis. They usually arise on the meningeal surface but (in contrast to adults) may grow as parenchymal lesions, presumably from meningeal cell rests. CT and MRI show an isointense or hyperintense lesion enhancing with contrast ([Fig. 59.10](#)). Most lesions are clinically benign, although pediatric tumors may show evidence of anaplasia. Surgery is the primary treatment modality. Radiotherapy is of uncertain value but has been used in patients with recurrent tumor, especially after unsuccessful attempts at re-resection. Meningioma may occasionally involve primarily the leptomeninges, and these tumors, also called meningeal sarcomas, tend to behave aggressively. Treatment has most often been with combined radiation and chemotherapy.

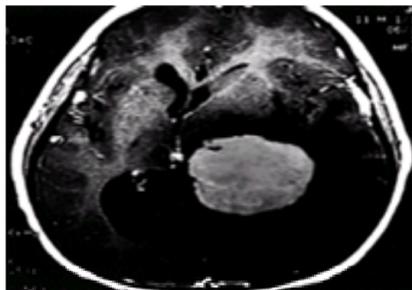

FIG. 59.10. Axial magnetic resonance image of a meningioma.

LATE EFFECTS OF TREATMENT AND QUALITY OF LIFE

Radiation therapy may be followed at 4 to 8 weeks by a transient “somnolence syndrome” of sleepiness, irritability, anorexia, and headache, lasting about a week. A much more serious complication is radiation necrosis, which develops in 0.1% to 5.0% of patients after conventional treatment at 50 to 60 Gy in daily fractions of 180 to 200 cGy. The onset may be within 3 months and usually by 3 years, although occasionally much later, and symptoms and signs are those of a recurrent intracranial mass, with possible seizures and progressive neuropsychological impairment. Surgical resection should be attempted; unresectable lesions may be treated with corticosteroids, but subsequent taper may be difficult. Children younger than 2 to 3 years are particularly susceptible to radiation injury because of incomplete development of the CNS. Large-vessel thrombosis is a rare complication of radiation therapy, occurring between 2 and 30 years after cranial irradiation. Treatment is symptomatic.

Endocrine dysfunction may follow irradiation to the hypothalamus and pituitary. Doses as low as 18 Gy may produce growth hormone deficiency, and doses above 36 Gy may cause hypothyroidism and gonadal dysfunction in more than half of patients receiving conventional whole brain irradiation. Precocious puberty was noted in nearly one-fourth of girls. The incidence of hypothyroidism appears to be considerably lower in children receiving hyperfractionated irradiation. Frank adrenal insufficiency is uncommon, but subtle abnormalities in adrenal function may be present. Children should be followed for measurement of linear growth, periodic thyroid function studies, and additional endocrine evaluation if there is precocious or delayed onset of puberty.

Radiation therapy may contribute to neurocognitive disorders in children with CNS tumors. Other factors include acute or chronic increased intracranial pressure, tumor mass effect, poorly controlled seizure disorders, and complications of surgery and chemotherapy. All these factors may have a negative impact on overall quality of life. Neurocognitive problems are more likely in children treated at a young age or with high doses of radiation, especially to cerebral cortical areas associated with higher functions. The effects may be progressive over several years and include attention deficit, impairment of short-term memory, and lowering of IQ. The anticipated decline in IQ can be estimated based on initial IQ, radiation dose, and age at time of irradiation. These children will generally require formal psychologic intervention and special education programs.

Chronic neurotoxicity of chemotherapy used in treating CNS tumors may include hearing loss (relatively common after cisplatin) and peripheral neuropathy (seen with vincristine and to a lesser extent cisplatin and etoposide). Restrictive lung disease and cardiac dysfunction may occur after spinal irradiation, and the risk could be increased by chemotherapy. Osteopenia was found in half of children surviving brain tumors, and bone pain may limit physical activity in these individuals; the cause is probably multifactorial. Chemotherapy may potentiate the deleterious effect of craniospinal irradiation on growth. There is an increased risk (approximately 3% to 5%) of second tumors after cranial irradiation, including meningiomas and sarcomas, arising 10 to 20 years after treatment. Secondary leukemia has been reported after chemotherapy with alkylating agents and etoposide.

CHAPTER 60. VASCULAR TUMORS AND MALFORMATIONS

ROBERT A. SOLOMON, JOHN PILE-SPELLMAN AND J. P. MOHR

[Vascular Malformations](#)
[Vascular Tumors](#)
[Suggested Readings](#)

The heterogeneous group of vascular lesions reviewed in this brief chapter includes a group of anomalies, some true vascular malformations, some acquired fistulas, and a few belonging to a category of neoplasms.

Vascular malformations

- Arteriovenous malformations
- Venous malformations
- Cavernous malformations
- Telangiectases
- Sturge-Weber disorder
- Sinus pericranii

Vascular tumors

- Angioblastic meningiomas
- Hemangiopericytomas
- Hemangioblastomas

VASCULAR MALFORMATIONS

Vascular lesions referred to as malformations (arteriovenous malformations, AVMs) of the brain have been confused with vascular neoplasms because the clinical course may be progressive and the angiographic picture is sometimes indistinguishable from a neoplasm of blood vessels. However, none are true neoplasms, at least showing no capacity for metastasis and the limited histologic data showing no signs of mitotic figures. Most are inferred to be congenital lesions, but some are arteriovenous fistulae acquired from trauma and arterial or venous occlusions.

Arteriovenous Malformations

AVMs, whether congenital or acquired, are limited to the brain, dura, or both. Those confined to the brain are the more common. Histologically, at the main site of linkage between the arteries and veins, there are no capillaries, the nidus consisting of a tangle of abnormal arteries and veins with interposed sinuses of irregularly sized vascular channels lacking a media and identifiable neither as arteries nor veins. Most are congenital, thought to grow with and displacing adjacent brain tissue. They may be limited to the brain surface, have their major focus in the subsurface white matter, be confined to the deep structures (e.g., basal ganglia, thalamus), lie in the cerebellum or the brainstem, and a few affect the arteries to the choroid plexus alone. Those on the brain surface lying in the borderzone between the major cerebral arteries typically draw supply from more than one of the adjacent cerebral arterial branches. Collateral from the adjacent dura may occur. Those that penetrate to the ventricular wall often draw collaterals from the deep vasculature supplying the basal ganglia. Venous drainage may be by superficial or deep venous systems. The threat to health is hemorrhage. The risk of bleeding approximates that of cerebral aneurysms but the morbidity differs, being less. Usually arising from the nidus, hemorrhage may displace adjacent brain with varying degrees of damage, vent into the ventricular system causing mainly a hemo- or hydrocephalus, or spread into the subarachnoid space. Typical subarachnoid hemorrhage may also occur from aneurysms commonly found along the path of intracranial vessels feeding the malformation. Hemorrhage occurs most commonly in the middle decades of life. Separately, AVMs may be associated with seizures or headaches. No distinctive features separate either the seizures or the types of headache (including migraine) from non-AVM causes ([Fig. 60.1](#), [Fig. 60.2](#) and [Fig. 60.3](#)).

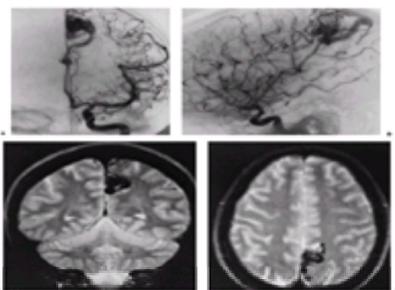

FIG. 60.1. Left parietal arteriovenous malformation (AVM). Anteroposterior (**A**) and lateral (**B**) subtraction films in the arterial phase of a left internal carotid injection show the anterior cerebral artery (ACA) supply and early superficial venous drainage of a left parietal AVM. Coronal (**C**) and axial (**D**) T2-weighted magnetic resonance images of the same patient show a serpiginous pattern of signal void representing flow in vascular structures. (Courtesy of Drs. J. A. Bello and S. K. Hilal.)

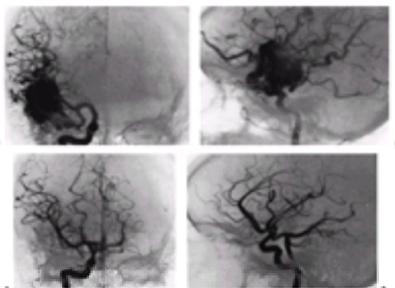

FIG. 60.2. Right temporal arteriovenous malformation (AVM). **A:** Anteroposterior view from arterial phase of right internal carotid arteriogram shows a large enhancing vascular lesion in right temporal region supplied by enlarged branches of right middle cerebral artery. **B:** Lateral view demonstrates prominent early draining cortical veins emanating from AVM. Postembolization anteroposterior (**C**) and lateral (**D**) views of right internal carotid arteriogram show interval disappearance of right temporal AVM with multiple metallic coils seen within right middle cerebral arterial feeders. Note normal filling of both anterior and both posterior cerebral arteries, thereby confirming increase in blood flow to normal brain structures. Patient did well after embolization with no complications. Follow-up definitive surgery found no evidence of flow within AVM, and the nidus was removed to prevent recurrence. (Courtesy of Drs. S. Chan and S. K. Hilal, Columbia University College of Physicians and Surgeons, New York, NY.)

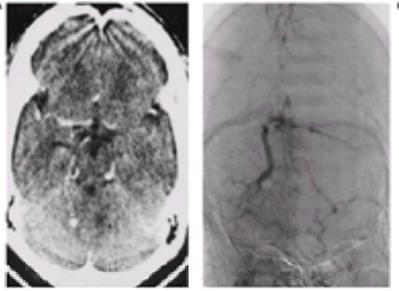

FIG. 60.3. Venous angioma. **A:** Postcontrast computed tomography (CT) demonstrates a round enhancing structure in the right cerebellar hemisphere, seen on contiguous axial sections as well, and therefore consistent with a single prominent vessel, “end-on.” This is the typical CT appearance of a venous angioma. **B:** An anteroposterior subtraction film in the venous phase of a vertebral angiogram shows medullary veins in the right cerebellar hemisphere converging toward a single vertically oriented draining vein, which corresponds to the vessel seen in cross section on CT. (The arterial phase was typically normal.) (Courtesy of Drs. J. A. Bello and S.K. Hilal.)

Computed tomography (CT) or magnetic resonance imaging detects acute hemorrhage; magnetic resonance imaging and magnetic resonance angiogram document the AVM, any prior major hemorrhage, intranidal aneurysms, and the main sources of supply. The vascular anatomy in cases intended for treatment is best defined by angiography, which should be reserved for such times ([Fig. 60.4](#) and [Fig. 60.5](#)).

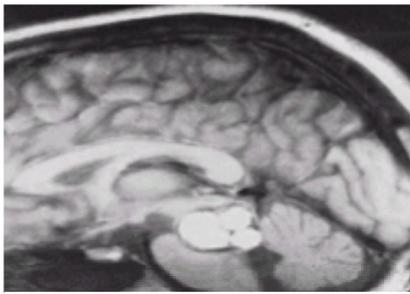

FIG. 60.4. Cavernous malformation, brainstem. Sagittal T1-weighted magnetic resonance imaging demonstrates a loculated-appearing midbrain lesion of increased signal intensity surrounded by ring of decreased signal intensity, which is characteristic of a subacute hemorrhage surrounded by a ring of hemosiderin. Cavernous vascular malformations typically show evidence of previous hemorrhage. (Courtesy of Drs. J. A. Bello and S. K. Hilal.)

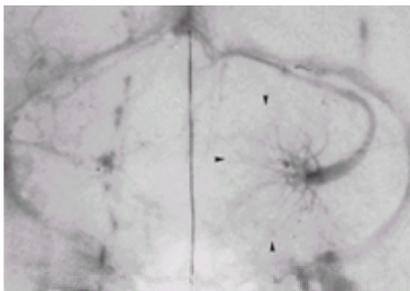

FIG. 60.5. Subtraction posterior fossa angiogram, venous phase. In this anteroposterior view, the characteristic venous malformation is demonstrated (*arrows*).

Because of the threat of disability from hemorrhage, AVMs should be approached with a plan for treatment. Intravascular occlusive therapy using fast-acting glues and other agents may occasionally obliterate some AVMs but more commonly lowers the operative risk by reducing the size and pressure within the malformation before surgery. Surgery is the most effective means of eliminating AVMs. For the smaller (less than 2.5 cm) deeply lying lesions not suitable for embolization or surgery, focused-beam radiotherapy (radiosurgery) is an alternative therapy, and experts currently debate the general applicability for larger lesions.

The vein of Galen malformation is a special AVM associated with the deep venous system, often with marked aneurysmal dilatation of the vein of Galen region. The arterial supply may be complex and difficult to occlude by intravascular or surgical techniques. These lesions are symptomatic in neonates or young children; severe shunting leads to cardiac failure and compression of the midbrain, which causes hydrocephalus. The currently accepted treatment of these lesions is embolization, occasionally followed by surgery.

Venous Malformations

Venous malformations (also deep venous anomalies) exist and have no apparent arterial supply. They may cause headaches, seizures, or, rarely, hemorrhage. Large venous channels may be seen on a prolonged high-volume contrast angiogram ([Fig. 60.6](#)). They are easily recognized using CT because of their contrast enhancement. They generally lie in the deep white matter and portions of the brainstem and cerebellum and are often diffuse, ill-defined, do not allow obliteration of arterial supply as the lesion is entirely venous, and are thus not amenable to safe surgical resection. They generally follow a benign course. The symptoms produced by the lesion are treated individually. Only under extenuating circumstances is surgical resection considered.

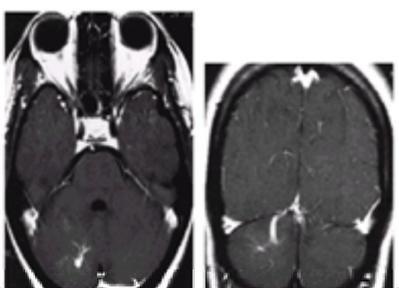

FIG. 60.6. Venous angioma. T1-weighted gadolinium-enhanced axial (**A**) and coronal (**B**) magnetic resonance scans demonstrate prominent vascular enhancement within the right cerebellar hemisphere with prominent venous radicles draining into an enlarged draining vein. This configuration is characteristic of venous angioma.

Cavernous Malformation

Cavernous malformations are highly focal usually small anomalies, and the histologically distinct cluster of tiny vessels of uniform size is the basis of the name "cavernous." The vessels are too small and the shunt is too limited for them to be seen on angiogram. They may cause a limited local hemorrhage, and it may recur, but major bleeding is uncommon. Multiple lesions have been documented in families. They may occur anywhere in the brain. Because of calcium content from inferred prior asymptomatic hemorrhage, the lesion may be visible on CT without contrast or enhance moderately with contrast. It may be mistaken for a vascular tumor, however, without displacement of the surrounding structure. Magnetic resonance imaging is characterized by a "target" appearance ([Fig. 60.7](#)). Seizures, headaches, or vague neurologic symptoms may occur. If hemorrhage has occurred and the lesion is readily accessible, surgery is usually recommended.

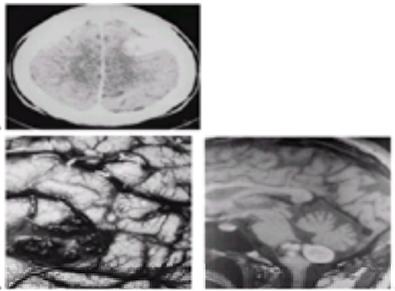

FIG. 60.7. **A:** Axial computed tomography demonstrates a cavernous malformation extending deep from the cortical surface. **B:** Operative exposure of cavernous malformation shows the cortical component of this lesion. **C:** Magnetic resonance imaging shows the characteristic variegated appearance of a cavernous malformation of the brainstem in a different patient.

Telangiectasia

Telangiectases are collections of engorged capillaries or cavernous spaces separated by relatively normal brain tissue. They are usually small and poorly circumscribed and may be found in any portion of the central nervous system. Telangiectases have a propensity for the white matter. They may be associated with telangiectasia of the skin; mucous membranes; and the respiratory, gastrointestinal, and genitourinary tracts, as in the *Rendu-Osler-Weber syndrome*. The associated pulmonary shunts may provide a path for septic material for brain abscess formation. These lesions infrequently lead to gross hemorrhage and fatality. For the most part, these are neurologic curiosities; they cannot be identified on angiography or CT and have no surgical significance. They are usually recognized only at autopsy.

Sturge-Weber Disease (Krabbe-Weber-Dimitri Disease)

The two cardinal features of Sturge-Weber disease (discussed elsewhere) are a localized atrophy and calcification of the cerebral cortex associated with an ipsilateral port wine-colored facial nevus, usually in the distribution of the first division of the trigeminal nerve. Angiomatous malformation in the meninges, ipsilateral exophthalmos, glaucoma, buphthalmos, angiomas of the retina, optic atrophy, and dilated vessels in the sclera may also be present. Any portion of the cerebral cortex may be affected by the atrophic process, but the occipital and parietal regions are most commonly involved.

In the atrophic cortical areas there is a loss of nerve cells and axons and a proliferation of the fibrous glia. The small vessels are thickened and calcified, particularly in the second and third cortical layers. Small calcium deposits are also present in the cerebral substance ([Fig. 60.8](#)), and rarely are there large calcified nodules. When an angioma is present, it is limited to the meninges overlying the area of shrunken cortex. It is now generally agreed that the atrophy and calcification of the cortex are not secondary to the angiomatous malformations of the leptomeninges.

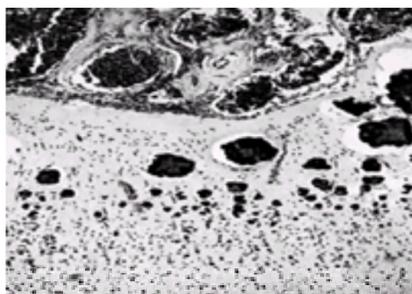

FIG. 60.8. Sturge-Weber syndrome. Angiomatous malformation in meninges and calcification in cortex. Hematoxylin and eosin stain. (Courtesy of Dr. P. Duffy.)

It is possible for the combination of a port wine facial nevus and localized cortical atrophy to exist without clinical symptoms, but in most patients, convulsive seizures are present from infancy. Mental retardation, glaucoma, contralateral hemiplegia ([Fig. 60.9](#)), and hemianopia are also present in most cases.

FIG. 60.9. Sturge-Weber disease. Right facial nevus in patient with convulsions and left hemiparesis. (Courtesy of Dr. P.I. Yakovlev.)

Sturge-Weber disease can be diagnosed without difficulty from the clinical syndrome. The presence of the cortical lesion can be demonstrated in most cases by the

appearance of characteristic shadows in the radiographs (Fig. 60.10). The calcified area in the cortex appears as a sinuous shadow with a double contour, showing both the gyri and sulci of the affected cerebral convolutions. The lesions in the occipital or parietal lobes are usually more definitely calcified than are those that occur in the frontal lobe.

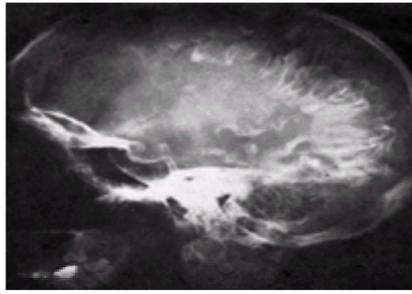

FIG. 60.10. Radiograph shows the intracerebral calcification in Sturge-Weber disease. (Courtesy of Dr. P.I. Yakovlev.)

The treatment of Sturge-Weber disease is essentially symptomatic. Anticonvulsive drugs are given for the seizures. Radiation therapy has been recommended, but there is no evidence that it is of any benefit. Hemispherectomy may control the convulsive seizures but is avoided because of a high complication rate.

Sinus Pericranii

Sinus pericranii is composed of thin-walled vascular spaces interconnected by numerous anastomoses that protrude from the skull and communicate with the superior longitudinal sinus. The malformation appears early in life and is soft and compressible; it increases in size when the venous pressure in the head is raised by coughing, straining, or lowering the head. It may enlarge slowly over a period of years. The external protuberance may be seen at any portion of the midline of the skull, including the occiput, but is most often found in the midportion of the forehead. Except for the external swelling, there are usually no symptoms. There may be occasionally a pulsating tinnitus, increased intracranial pressure, or a variety of cerebral symptoms. Radiographs show a defect of the underlying bone, through which the lesion communicates with the longitudinal sinus.

VASCULAR TUMORS

The three forms of the neoplastic lesions may be variations of the same tumor. By light microscopy they are indistinguishable; however, the hemangioblastoma is confined to the posterior fossa and has no dural attachment. The angioblastic meningioma is grossly identical to other meningiomas but has a significant dural attachment and is located either above or below the tentorium. The hemangiopericytoma originates in other areas of the body, presumably from blood vessel elements.

Angioblastic Meningiomas

These tumors are included here because they are histologically similar to the other tumors reviewed in this section.

Hemangiopericytomas

The hemangiopericytoma arises from the endothelial elements of blood vessels and is recognized elsewhere in the body. It is histologically similar to the angioblastic meningioma and the hemangioblastoma, especially when the vascular spaces are separated more widely and the stroma cells are collected about the vascular spaces. It may be that the pial and endothelial cells are interconvertible.

Hemangioblastomas

Hemangioblastomas are composed of primitive vascular elements and are rare, accounting for 1% to 2% of all intracranial neoplasms. They occur at all ages, but young and middle-aged adults are more frequently afflicted. In children, they are almost as common in the posterior fossa as are meningiomas (Fig. 60.11). Symptoms are generally present for approximately a year before the diagnosis is made. Male incidence predominates. *Von Hippel-Lindau disease* is defined by the coexistence of hemangioblastoma and multiple angiomas of the retina, cysts of the kidney and pancreas, and, occasionally, renal cell carcinomas and capillary nevi of the skin. There is a familial incidence in 20% of cases. Only 10% to 20% of the hemangioblastomas, however, are associated with the systemic signs known as the Lindau syndrome. All gradations of clinical expression between the full syndrome and incomplete manifestations may be seen in the same family. Pheochromocytoma and syringomyelia may occur, especially when the hemangioblastoma is in the spinal cord. Polycythemia disappears after resection of the neoplasm, but returns with recurrence; an erythropoietic substance from the cystic fluid has been identified.

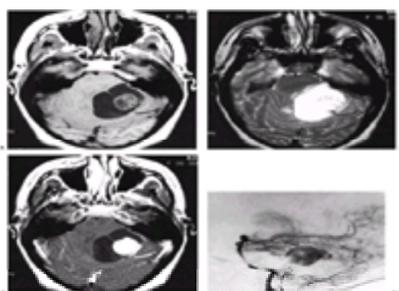

FIG. 60.11. Cerebellar hemangioblastoma. T1-weighted (A) and T2-weighted (B) axial magnetic resonance scans demonstrate a large fluid-filled cyst in the left cerebellar hemisphere that appears dark on T1 scan and bright on T2 scan. A mass of heterogeneous signal intensity present within the left posterior aspect of the cyst appears attached to the wall of the cyst. Note prominent blood vessel projecting to the left from the posterior aspect of this mural nodule, probably representing draining vein. C: T1-weighted axial magnetic resonance scan with gadolinium enhancement shows marked enhancement of mural nodule and no enhancement of the cyst. Note prominent enhancement of enlarged draining vein. D: Lateral view from late arterial phase of conventional vertebral arteriogram shows densely enhancing mass in posterior fossa with posterior draining vein. (Courtesy of Drs. S. Chan and A. G. Khandji, Columbia University College of Physicians and Surgeons, New York, NY.)

These tumors are predominantly in the cerebellum and are often associated with large cysts that are surrounded by a glial wall containing yellow proteinaceous fluid, the result of secretion and hemorrhage from the tumor. It resembles the cyst and mural nodule of the cystic cerebellar astrocytoma but has a distinctive vascular appearance on an angiogram. They may be multiple, in which case difficulty in achieving a cure or total removal of the lesion may be encountered. They have no dural attachment and rarely occur in the supratentorial area, where they may be confused with angioblastic meningiomas.

The most common site of the hemangioblastoma is in the paramedian cerebellar hemispheric area; the second most common site is the spinal cord.

Hemangioblastomas also occur in the medulla in the area postrema.

Clinical features of the hemangioblastoma of the cerebellum are symptoms typical of any cerebellar mass, such as headache, papilledema, and ataxia. When the tumor is multiple, lesions may involve the brainstem and upper cervical cord as well. Hemangioblastoma of the cerebellum can be diagnosed without difficulty from the CT and posterior fossa angiogram. The diagnosis is even more certain when the tumor is associated with angiomas of the retina and polycythemia.

Treatment is surgical, with evacuation of the cyst and removal of the mural nodule; 85% of all patients who undergo this treatment are alive and well 5 to 20 years after surgery. There is a high incidence of recurrence, however, if the tumor is partially removed or is associated with multiple tumors.

EPIDEMIOLOGY

Up to 35% of all patients with systemic cancer have central nervous system (CNS) metastases. The incidence may be increasing because longer survival may permit a tumor to grow in sanctuary sites such as the brain. Brain metastases are 10 times more common than primary brain tumors; 12,000 people die with primary brain tumors and 130,000 die with brain metastases each year.

DISTRIBUTION

About 66% of CNS metastases affect the parenchyma; spread to leptomeninges, calvarium, or dura is less common. In the spine, the vertebrae are most frequently affected. Some systemic tumors rarely metastasize to the brain. For instance, prostate carcinoma affects the vertebrae and compresses the spinal cord but rarely spreads to the brain or cord parenchyma. Dural metastases arise from prostate or breast carcinoma, and sarcomas.

In *parenchymal metastases* on computed tomography (CT), 49% of patients with brain metastasis have a single lesion, 21% have two, and 30%, three or more. Therefore, 70% of brain metastases can be treated by focal therapy. The tumor distribution parallels blood flow to the brain; about 3% affect the brainstem, 15% the cerebellum, and the others are supratentorial. Some primary tumors show a predilection for particular areas. Pelvic tumors (uterus, colon, or prostate) tend to metastasize to the cerebellum and breast tumors to the pituitary. Breast tumors or melanoma metastasize early to the lungs and enter the systemic circulation. They have the highest incidence of parenchymal brain metastases and tend to be multiple.

Pituitary metastases are uncommon; breast carcinoma accounts for 50%. They are often found incidentally at autopsy in 1.8% of all cancer patients and 15% of patients with breast cancer. One percent of patients undergoing transsphenoidal surgery for a symptomatic pituitary tumor have metastatic carcinoma, and 80% of pituitary metastases affect the posterior pituitary gland or infundibulum. Incidental pituitary metastases are microscopic; symptomatic cases show a characteristic triad of diabetes insipidus, headache, and visual loss. A pituitary mass in a patient with diabetes insipidus and known carcinoma should be considered metastatic until proven otherwise. In contrast to the slow progression of symptoms from pituitary adenoma, manifestations of a metastasis evolve in days or weeks. Pineal spread is usually discovered at autopsy in patients with extensive systemic malignancy. Leptomeningeal seeding frequently accompanies pineal metastases because the tumor sits in the suprasellar cistern and sheds cells into the subarachnoid space.

Dural and subdural metastases are most common in breast or prostate cancer, melanoma, leukemia, neuroblastoma, or lymphoma. Symptoms are produced by compression of the superior sagittal sinus or cranial nerves. Leptomeningeal metastases are most common in patients with leukemia, lymphoma, or carcinoma (breast, lung, melanoma). Perineural metastases usually affect the trigeminal nerve, facial nerve, greater auricular nerve, or oculomotor nerve. Squamous carcinoma, basal cell carcinoma, and carcinoma of the minor salivary glands are most commonly responsible.

In *calvarial and base of the skull metastases*, the most common tumor that metastasizes to the skull base is breast carcinoma, followed by lung and prostate. About 44% of these patients have had bone metastases somewhere else. Five syndromes are recognized. For the clinician, any of these syndromes should raise concern about metastases, even if a primary cancer is thought to have been cured. The *orbital syndrome* comprises supraorbital pain, blurred vision, and diplopia. Examination reveals proptosis, ophthalmoplegia, or decreased ophthalmic trigeminal sensation. In the *parasellar syndrome*, cavernous sinus metastases cause frontal headache and ophthalmoparesis. Papilledema is present in a third of the patients; visual loss is less frequent. Primary neoplasms, Tolosa-Hunt syndrome, and carotid artery aneurysms are in the differential diagnosis. In the *middle fossa syndrome*, involvement of the Gasserian ganglion or branches of the trigeminal nerve leads to sensory loss, paresthesias, or pain in the V2 and V3 distribution; lancinating pain is atypical. In the *jugular foramen syndrome*, unilateral occipital, postauricular, or glosopharyngeal pain is followed by hoarseness, dysphagia, and sometimes syncope. By the time of diagnosis, most patients have glosopharyngeal, vagus, and accessory nerve dysfunction, including paresis of the palate, vocal cords, and the sternocleidomastoid. Decreased hearing and facial paralysis indicate extension into the petrous bone. *Occipital condyle syndrome* consists of occipital pain worse on flexion of the neck, with or without a twelfth cranial nerve palsy.

Spinal metastases are described below.

PRIMARY TUMORS LEADING TO CENTRAL NERVOUS SYSTEM METASTASES

Systemic neoplasms vary in propensity to metastasize to the brain. The most common primary neoplasms are melanoma, lung carcinoma, breast carcinoma, and leukemia ([Table 61.1](#)). Prostate, genitourinary malignancies, some sarcomas, and malignancies from the endocrine glands or digestive tract rarely spread to the brain.

Type of malignancy	No. of expected deaths/1000	Intracranial metastases		Brain metastases	
		Frequency (%)	n ^a	Frequency (%)	n ^a
Lung	140,000	11	41,000	35	12,100
Colorectum	57,000	8	4,500	6	1,400
Breast	40,500	11	22,000	11	1,600
Soft-part sarcoma	22,000	6	2,300	1	400
Prostate	20,000	17	4,000	4	2,100
Renal-cell carcinoma	20,000	7	1,700	2	700
Gastrointestinal	20,000	6	1,000	6	1,400
Uterine carcinoma	20,000	21	4,200	17	3,500
Lymphoma	20,000	12	4,000	5	1,000
Leukemia	18,000	46	8,300	8	1,500
Head and neck	11,000	18	2,000	7	800
Melanoma	4,000	13	4,400	48	3,300

TABLE 61.1. FREQUENCY AND NUMBER OF ESTIMATED CASES OF INTRACRANIAL AND BRAIN METASTASES (USA)

Melanoma

About 46% of patients develop brain metastases, 96% have systemic disease, 75% of the brain metastases are multiple, and 33% to 50% show hemorrhage ([Fig. 61.1](#)). The risk of brain metastasis is higher with deeper primary lesions or head, neck, or shoulder tumors.

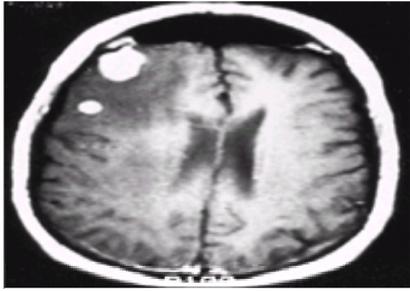

FIG. 61.1. Melanoma brain metastases. Noncontrast-enhanced T1-weighted magnetic resonance image of patient with recurrent melanoma. The metastases are high signal because of either the presence of melanin within the tumor or hemorrhage. Note the extensive surrounding edema.

Lung Cancer

At the time of diagnosis, 10% of patients have brain metastases, which may be asymptomatic; 20% develop brain metastases during treatment; and 50% of those who survive 2 years develop them. Forty percent of patients with small cell lung carcinoma develop brain metastases, as do 28% of those with adenocarcinoma of the lung. About 50% of patients with lung cancer have brain metastases at autopsy.

Breast Carcinoma

This is the most common source of brain metastases in women, seen in 20% of women with this tumor. In contrast to brain metastases from other solid tumors, two-thirds of these patients die of the intracranial disease. Several intracranial compartments may be affected simultaneously: parenchyma, dura, leptomeninges, or a combination. Benign meningiomas are disproportionately frequent in women with breast carcinoma, so a dural-based mass in such a patient may require a biopsy or serial imaging to clarify the diagnosis.

Gynecological malignancies uncommonly metastasize to the CNS. The most characteristic is the rare choriocarcinoma.

Colon Cancer

An infrequent cause of brain metastases, colon cancer affects 4% of patients. Most patients have extensive systemic disease; 85% have pulmonary metastases. Posterior fossa lesions are overrepresented, affecting 35% of patients. In patients with liver metastases, the incidence of brain metastases is lower, possibly related to a filtering effect. CT may show a hyperdense lesion, hypointense on T2-weighted magnetic resonance images, perhaps caused by coagulative tumor necrosis.

Carcinoma of an Unknown Primary

This represents 8% of patients with brain metastasis. The site of origin is eventually identified in 25% of the cases, and in half of these, the primary tumor is lung carcinoma. In contrast to clinically evident systemic tumors, morbidity and mortality are related to the brain metastasis, and aggressive treatment of the brain lesion is indicated.

DIAGNOSIS

Clinical Diagnosis

Symptoms are similar to those of any space-occupying lesion, including motor impairment (66%), headache (53%), mental changes (31%), papilledema (26%), ataxia (20%), and seizures (15%). Multiple brain metastases can mimic encephalopathy or dementia. Headache may be caused by the tumor, edema, hydrocephalus, sinus thrombosis from dural metastases, or leptomeningeal metastasis. Pain-sensitive structures vulnerable to distortion include the dura, tentorium, and cranial nerves. Seizures are the first symptom in 15% to 20% of patients, but up to 10% of additional patients develop seizures later. Seizures occur more frequently with multiple, frontal, or temporal metastases. Tumor histology does not correlate with epileptogenicity. It is debatable whether all patients with metastases should be treated prophylactically. In a double-blind, prospective, randomized trial of patients with brain metastases with no prior seizure, there was no significant difference in seizure frequency of those who received valproic acid or placebo. Anticonvulsant therapy is not without risk, including a 4% incidence of drug allergy with phenytoin, elevation of hepatic enzymes, alteration of metabolism of dexamethasone and chemotherapy, and the risk of Stevens-Johnson syndrome when combined with radiotherapy. Other metastatic symptoms include stroke-like episodes in 10% of patients with cerebral metastases and attributed to intratumor hemorrhage or sudden obstruction of cerebrospinal fluid (CSF) flow. Hemorrhage occurs most commonly in choriocarcinoma, melanoma, and lung and renal cell carcinoma.

Radiographic Diagnosis

Magnetic resonance imaging (MRI) with contrast administration of gadolinium is the most sensitive diagnostic method for detection of either intraparenchymal or leptomeningeal brain metastases, particularly for posterior fossa lesions. It is also best for differentiating intraparenchymal and dural-based lesions. MRI may identify multiple lesions when CT shows only single lesions that might be considered candidates for surgical therapy. CT is better in detecting lytic bony lesions.

Most brain metastases appear as round well-circumscribed lesions, hypointense on T1-weighted images and hyperintense on T2.

Up to 90% enhance after gadolinium. Lesions as small as 3 mm can be detected on contrast-enhanced images but may be invisible on precontrast. T2-weighted images are useful for identifying hemorrhagic metastases and surrounding edema that might be mistaken for an infarct. Enhancement may be heterogeneous. Ringlike enhancement is also seen in brain abscess, but abscesses typically have thinner rims and may show a target-type sign.

Histology cannot be determined by MRI alone. Malignant melanoma is an exception: The lesions are isointense to hyperintense on T1-weighted images and hypointense on T2-weighted images. Colon carcinoma metastases may display a characteristic hypointensity on T2-weighted images. Some tumors spread to the brain with little reaction in surrounding tissue, so-called miliary brain metastases, seen with neuroectodermal tumors ([Fig. 61.2](#)). The MRI pattern is caused by the perivascular distribution of lesions with multiple tumor nodules, which may not be evident on contrast T1-weighted MRI, appearing only as T2-weighted changes.

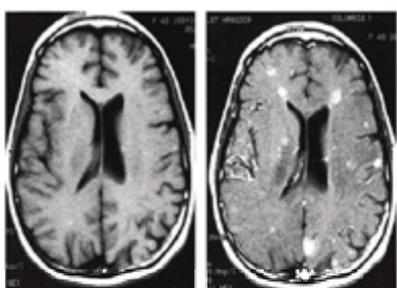

FIG. 61.2. Miliary brain metastases. Noncontrast-enhanced (A) and contrast-enhanced (B) magnetic resonance images of a patient with breast cancer. Note that the nonenhanced scan appears almost normal. The contrast-enhanced scan shows greater than 20 separate metastatic lesions with no significant surrounding edema.

This patient was neurologically normal at the time of this scan, which was performed after a cervical spine magnetic resonance image showed a cerebellar metastasis.

About 14% of brain metastases are hemorrhagic, mimicking a stroke. The hemorrhage is usually intraparenchymal but may be subarachnoid, intraventricular, or subdural. Multiple sites of intracerebral hemorrhage argue strongly in favor of metastatic disease. Metastases are more likely to bleed than primary brain tumors. Hemorrhage may be spontaneous or due to thrombocytopenia from chemotherapy or a coagulopathy. If the platelet count is less than 20,000, hemorrhage may occur in areas of the brain unaffected by tumor spread. Calcification of the metastasis may be seen with colon, lung, or breast carcinoma. Magnetic resonance angiography may show the relationship of the tumor to major blood vessels before surgery or distinguish hemorrhagic metastases from vascular malformations. Positron emission tomography with fluorine-18 fluorodeoxyglucose may distinguish recurrent tumors from radiation necrosis.

Clinical Evaluation

In the patient without a known primary tumor and suspected brain metastases, a focused screening workup is appropriate. Attention is directed to a chest radiogram or chest CT, followed by abdominal or pelvic CT or endoscopy if gastrointestinal symptoms are evident. Physical examination should address possible breast, testicle, prostate, or rectal lesions. Stool should be examined for occult blood. If imaging suggests a melanoma, consider acral lentiginous melanoma on palms or soles, melanoma of the uveal tract, or subungual tumor. If screening is unrevealing and a single lesion is surgically accessible, resection is performed for diagnosis and treatment. If multiple brain lesions are present, a stereotactic brain biopsy is preferred.

Differential Diagnosis

When a patient with a primary neoplasm develops neurologic symptoms, other conditions may mimic metastases. In patients immunosuppressed by chemotherapy, pulmonary infections may lead to septic emboli and *brain abscess*. The diagnosis may be suspected when location is atypical for a metastases, such as the basal ganglia. Multiple small contrast-enhancing lesions may be seen in *tuberculosis* or *fungal abscesses*. On MRI, abscesses have thin-walled rings of contrast enhancement, different from the thicker nodular enhancement with metastases. Multifocal gliomas may mimic brain metastases.

Demyelinating disease can occasionally appear on CT or MRI as large contrast-enhancing lesions with mass effect. The clinical disorder may be acute and monophasic rather than the typical relapsing and remitting pattern of multiple sclerosis. Histologically, large reactive astrocytes seen in active demyelinating lesions may be misinterpreted as neoplastic.

Delayed *radiation necrosis* can cause a contrast-enhancing mass, which may enlarge on subsequent scans. *Stroke* may mimic metastases clinically and radiographically, with discrete lesions and contrast enhancement. With time, the infarct improves radiographically. Dural metastases of prostate or breast carcinoma may mimic *meningiomas*. An unusual phenomena is "tumore-in-tumori," a systemic malignancy metastasizing to already existing primary intracranial tumor, favored by the high blood flow to the recipient tumor.

Pathophysiology

In 1889, Paget proposed the "soil-seed" hypothesis, that tumors metastasize preferentially to organs that provide a favorable environment. In 1928, Ewing speculated that metastases are directly related to the vascular supply of the target organ. The pattern is not random, and organs similar in developmental origin have a similar propensity for metastasis. In the CNS, metastases to cortex and white matter correlate with metastases to leptomeninges, another neuroectodermally derived tissue, but not with metastases to dura, which originates from mesoderm. In animal models, some tumors show predilection for specific organs, providing evidence against a purely hemodynamic theory.

Spread to the brain occurs when the primary tumor sheds tumor emboli into the circulation. The lung effectively filters larger tumor emboli, and a pulmonary lesion is present before a brain metastasis. An embolic mechanism is also suggested by higher incidence of brain metastases in watershed vascular regions than in other areas of the brain. Metastases may bypass the lungs via a patent foramen ovale or with pelvic and abdominal tumors, when cells pass through the Batson plexus to the paravertebral and intracranial venous plexi. Contiguous spread to adjacent bony structures is another mechanism with tumors expanding locally and invading the CNS secondarily.

Metastasis is a multistep process that includes passage of malignant cells to the target organ, thrombosis in capillaries, adherence to endothelial cells, invasion of the subendothelial matrix, digestion of the basement membrane by proteolytic enzymes, and passage of tumor cells into the interstitial space. The first step involves cell attachment to the endothelium at the target site. For invasion to proceed, proteolytic enzymes then degrade the extracellular matrix and permit migration into surrounding tissues. Host cellular inhibitors of invasion (metalloprotease inhibitors) control extracellular matrix degradation. Direct cell-cell interactions or interactions between tumor cells and basement membrane may influence the organ specificity of metastases. In the early stages, tumor metastasis probably depends on paracrine growth factors, but as the malignancy advances, it develops autocrine means of growth stimulation. This parallels the clinical observation that in the early metastatic stage, tumors may show restricted organ distribution, but in the latter stages tumors may metastasize freely to multiple organs.

TREATMENT

Among patients with brain metastases, the lesions are lethal in less than half. In most, survival is determined by responsiveness of systemic tumor. Therapy is evaluated by local control and by overall survival. Corticosteroids were first used in the 1960s to decrease the permeability in the abnormal blood vessels surrounding metastases, reducing tumor edema or radiation-related edema. Corticosteroids often reverse neurologic symptoms within 24 hours in 80% of patients. Dexamethasone is used most often because of its low mineralocorticoid activity. Steroids are usually given during the course of radiation, at the lowest dose that controls neurologic symptoms. Twenty percent of patients take steroids chronically to reverse or stabilize neurologic symptoms. Even when therapy has failed and patients are moribund, steroids may relieve the headaches or vomiting of increased intracranial pressure.

Radiotherapy improves neurologic symptoms in 49% to 93% of patients. The degree of neurologic recovery is inversely proportional to the severity of symptoms before irradiation. External whole brain irradiation is given for either multiple brain metastases or single surgically inaccessible lesions. The goal of whole brain radiotherapy is to eradicate microscopic foci of tumor. Radiotherapy is palliative, prolonging survival from an average of 1 month without treatment (2 months with corticosteroids) to 4 to 6 months or more. Response is best in patients with breast carcinoma, those with a long interval between diagnosis of systemic tumor and brain metastases, or those with limited extracranial disease. A dose of 30 Gy is usually administered in 10 daily fractions of 0.3 Gy; higher doses are not more effective. Even with radiotherapy, fewer than 10% of patients survive 2 years; metastasis causes death in about 50%. It is uncertain whether radiotherapy improves the ultimate prognosis for single brain metastases that have been surgically resected. Radiosensitive tumors include germ cell tumors, lymphoma, and small cell lung cancer. Radioresistant tumors include melanoma, renal cell carcinoma, colon, and thyroid.

Brain metastases are usually well demarcated from the parenchyma, allowing complete removal and local control. Surgery may also provide a diagnosis when histology is not known. In a few patients, a single brain metastasis is the only evidence of spread from lung cancer. In this situation, surgery is elected for both the pulmonary lesion and the brain metastasis. Survival up to 7 years has been reported. Among 231 patients with non-small cell lung carcinoma who underwent resection for brain metastases, survival was shorter with incomplete resection of the primary brain tumor, infratentorial location, presence of systemic metastases, or age older than 60 years. Patients with single brain metastases who are treated with both surgery and radiotherapy remain functionally independent longer (median 38 versus 8 weeks), have a longer time to recurrence (more than 59 versus 21 weeks), and have a longer survival (40 versus 15 weeks) compared with those treated with radiation alone.

Chemotherapy has a limited role in treating brain metastases, which may be related to lack of chemosensitivity. Also, brain metastases often appear after primary chemotherapy has failed and the tumor has become resistant to effective agents. Nevertheless, brain metastases of breast, small cell carcinoma of the lung, or choriocarcinoma may respond.

With improved survival of patients with small cell lung cancer, more of them develop brain metastases. In 17% of patients, the CNS is the first site of failure. Prophylactic cranial irradiation is controversial, although studies abound in favor or against it. In one study, the 2-year cumulative incidence of brain metastases dropped from 47% to 10%, but there was no improvement in overall survival. In adenocarcinoma or large cell carcinoma of the lung, prophylactic cranial irradiation did

not alter overall survival, but it delayed the onset of brain metastases. Long-term survivors may develop a syndrome of leukoencephalopathy.

Radiosurgery was developed by Leskell in 1951 in an attempt to deliver high doses of radiotherapy to a confined region of brain. The spherical nature and defined borders of brain metastases make them ideal candidates. Also, multiple lesions can be treated with minimal dose overlap. Radiosurgery is administered using a gamma knife or linear accelerator. Radiosurgery has been used for either single or multiple brain metastases before whole brain radiotherapy, at diagnosis, or at the time of progression after conventional radiation. Radiosurgery may reduce the incidence of treatment-related leukoencephalopathy, particularly for patients with no evidence of active systemic disease. The local control rate with radiosurgery is 88%, about twice as much as the 45% local control rates with whole brain radiation. Melanoma and renal cell carcinoma, traditionally resistant to whole brain radiotherapy, are paradoxically among the tumors that respond most favorably to radiosurgery (Fig 61.3). Interstitial radiation allows treatment of defined lesions, sparing the surrounding brain. Radioactive seeds are placed in the tumor bed, which then receives local continuous radiation. Iodine-125 is used most often to treat either recurrent or newly diagnosed brain metastases.

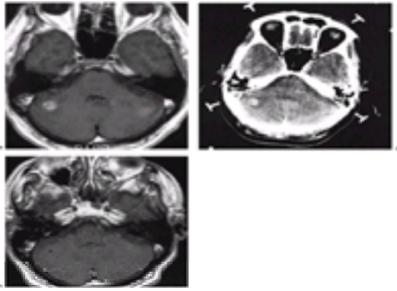

FIG. 61.3. Successful radiosurgical treatment of renal cell carcinoma. **A:** Contrast-enhanced magnetic resonance image shows a 1-cm right cerebellar hemisphere metastasis. **B:** Contrast-enhanced computed tomography in stereotactic frame for radiosurgery treatment planning. **C:** Contrast-enhanced magnetic resonance image 8 months after radiosurgery shows complete disappearance of the previous metastasis. All that remains is a focal area of atrophy.

CARCINOMATOUS MENINGITIS

Leptomeningeal metastasis develops in 4% to 15% of all patients with cancer. The increased incidence is attributed to improved survival of patients with cancer. Solid tumors are most commonly associated; breast cancer accounts for 12% to 34% of all patients, followed by lung cancer (10% to 26%), melanoma (17% to 25%), gastrointestinal cancer (4% to 14%), non-Hodgkin lymphoma, and acute lymphocytic leukemia. The primary site is unknown in 7% of cases. Patients usually have systemic disease at the same time; otherwise, the systemic tumor reoccurs within weeks of diagnosis of the carcinomatous meningitis.

Pathogenesis

Metastatic cells may reach the leptomeninges by various routes: hematogenous dissemination, spread from bone metastases, dissemination via the perivascular space, or along perineural spaces. There is a good correlation, with most systemic malignancies, between the development of osseous metastases and carcinomatous meningitis. Spread can develop via transgression of the dura through a primary extension from a vertebral, paravertebral, or calvarial lesion (Fig. 61.4). Tumor cells bind to the endothelial cells, extravasate or form a thrombus inside the lumen, and eventually disrupt the endothelium. Cells in the subarachnoid space spread along the leptomeninges to form perivascular cuffs, enter the Virchow-Robin spaces, and may penetrate the pia to involve the brain. Pathologically, the disease is characterized by diffuse infiltration of the leptomeninges. Hydrocephalus arises if tumor nodules obstruct the ventricles or basal cisterns. In the spinal cord, tumor infiltration is most prominent over the dorsal cord or cauda equina.

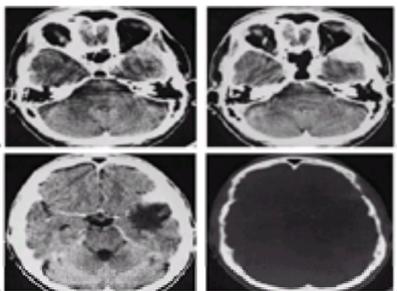

FIG. 61.4. Calvarial and epidural metastases. Precontrast (**A**) and postcontrast (**B**) axial computed tomographies demonstrate that the anterior wall of the middle cranial fossa is missing; it is replaced by an enhancing metastasis from breast carcinoma with an epidural component anterior to the left temporal lobe. The patient had left V1 sensory loss. Higher postcontrast cut (**C**) and bone window (**D**) at the same level demonstrate extension of the epidural metastasis. Transdural involvement is suggested by the prominent white matter edema in the underlying temporal lobe, with effacement of the left sylvian fissure due to mass effect. Note the extensive calvarial involvement in **D**. Malignant cells were recovered from cerebrospinal fluid, thus indicating coexistent meningeal carcinomatosis. (Courtesy of Drs. J.A. Bello and S.K. Hilal.)

Diagnosis

Symptoms and signs vary because the disease affects all levels of the CNS. Cerebral symptoms include headache (75%), mental status changes (65%), difficulty walking (27%), nausea and vomiting (22%), and seizures (11%). Cranial nerve symptoms include diplopia (30%), facial weakness (27%), hearing loss (12%), optic neuropathy (8%), and trigeminal neuropathy (8%). Spinal findings comprise reflex asymmetry (86%), limb weakness (73%), paresthesias (42%), radicular pain (26%), and sphincter dysfunction (16%).

CSF abnormalities include elevated pressure (42% to 72%), pleocytosis (64% to 77%), elevated protein (79% to 91%), and low glucose (41% to 77%). Proof of diagnosis is the demonstration of neoplastic cells in the CSF (Fig. 61.5). Repeated spinal punctures are often needed. In about 5% of patients, CSF cytology is positive when fluid is sampled from the ventricles or cisterna magna but not from the lumbar compartment. The first lumbar CSF examination shows neoplastic cells in 55%, rising to 80% after a second tap. Twenty-nine percent of patients with abnormal cytology have no CSF pleocytosis. Normal cytology does not exclude the disease; 41% of patients with carcinomatous meningitis at autopsy had a normal antemortem CSF.

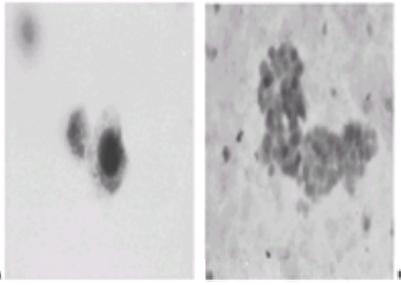

FIG. 61.5. Malignant cells in spinal fluid. Formalin-fixed millipore filtrates of lumbar cerebrospinal fluid in two patients with meningeal spread of neoplasm. **A:** Isolated large cells with increased nuclear-to-cytoplasm ratio and fine clumps of cytoplasmic pigment in a patient with meningeal carcinomatosis due to malignant melanoma (hematoxylin stain, $\times 450$). **B:** A clump of cohesive cells in patient with a primitive neuroectodermal tumor and extensive meningeal seeding (hematoxylin stain, $\times 180$).

Cranial CT findings include sulcal enhancement (21%), ependymal enhancement (75%), subarachnoid enhancing nodules (29%), intraventricular nodules (10%), and hydrocephalus (10%) (Fig. 61.6). Coexistent CNS metastases include parenchymal lesions (25% to 40%), dural metastases (16% to 37%), epidural cord compression (1% to 5%), and nodular leptomeningeal disease (10% to 15%). Head MRI with contrast can detect meningeal tumor in about 50% of patients with negative CSF cytology and no spinal symptoms and in up to 92% of those with positive CSF cytology. Head MRI is more sensitive than CT but both are often false negative (30% by MRI and 58% by CT).

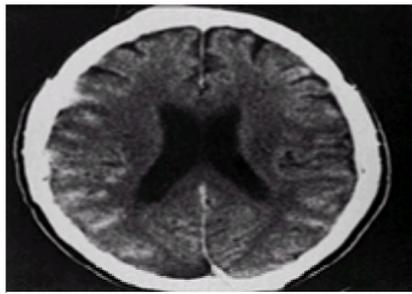

FIG. 61.6. Meningeal carcinomatosis. An axial contrast-enhanced computed tomography demonstrates abnormal sulcal enhancement causing sulcal effacement in a patient with metastatic breast carcinoma.

CT myelography findings include thickened nerve roots, nerve root filling defects, block of CSF flow, and subarachnoid nodules (Fig. 61.7). Spinal MRI shows pial enhancement along the cord. CT myelogram is better in detecting cord enlargement; spinal MRI with contrast shows subarachnoid nodules, intraparenchymal cord tumor, or epidural cord compression.

FIG. 61.7. Meningeal carcinomatosis. Myelogram and autopsy specimen of spinal cord from same patient with meningeal carcinomatosis. Note the intradural filling defects in the myelogram (**A**) that correspond to tumor nodules (*arrows*) seen on multiple nerve roots and thoracic spinal cord in pathologic specimen (**B**).

Radionuclide CSF flow studies with ^{111}In -DTPA injected into either the ventricles or lumbar CSF compartment is abnormal in 40% of patients. It can determine whether there is homogeneous distribution of intrathecal chemotherapy.

The following are recommended for patients with documented carcinomatous meningitis: head CT or MRI to show areas of bulky disease and the presence or absence of hydrocephalus, CT myelogram or spine MRI, and radionuclide flow study is performed in some institutions. Suspected cases should have at least two lumbar punctures. If negative, sampling can be done from the cisternal or intraventricular compartments.

Treatment

Meningeal carcinomatosis affects the entire neuraxis, and treatment must encompass all CSF compartments. Treatment is palliative. Radiotherapy is given to subarachnoid tumor nodules or intraparenchymal metastases, but craniospinal radiotherapy is not given routinely because of myelosuppression. Radiotherapy can be given to sites of CSF obstruction to provide homogeneous distribution of intrathecal chemotherapy.

Systemic chemotherapy is not routine, because of the limited CSF penetration of most agents. Meningeal lymphoma, breast, or lung cancer can be treated with systemic chemotherapy and radiation to the focal areas of disease. Patients with symptomatic hydrocephalus that does not respond to focal radiation require CSF shunting. Frequently, an intraventricular catheter and a subgaleal reservoir are installed for intrathecal chemotherapy. Intrathecal chemotherapy is limited to three agents (methotrexate, cytosine arabinoside, and thiopeta). Cytologic responses are seen in 60% of patients to first-line intrathecal therapy, in 29% to second, and in 13% to third-line treatment. The ventricular route achieves more uniform drug distribution than lumbar injections. Triple-agent therapy may give better responses and improved survival than single agents. Most complications of intraventricular treatment are transient and characterized by aseptic meningitis (43%). Patients may experience myelosuppression, particularly if they are given concurrent systemic therapy. A dreaded complication is chemotherapy-related leukoencephalopathy. Novel therapies include gene therapy with the herpes virus thymidine kinase gene, which increases survival in experimental neoplastic meningitis in rats. Intrathecal application of cytokines has been tested for interleukin-2, interferon- α , and lymphocyte-activated killer cells, and clearance of neoplastic cells have been observed in humans. Median survival of meningeal carcinomatosis is 6 months, but treatment may prevent neurologic deterioration. Prognosis is worse with widespread systemic disease, CSF block, and coexistent bulky CNS metastases. Sixty percent of patients die of progression of the systemic cancer, and 10% of treatment-related complications.

SPINAL METASTASES

Spinal involvement is seen at autopsy in 60% of patients with breast cancer and in 67% of living patients with prostate cancer. Small cell carcinoma of the lung spreads to the spine in 40% of all cases. Vertebral metastases cause epidural cord compression in 5% of patients, usually with widespread malignancy; in about 3% cord compression is the first sign of metastatic disease. The most common site of compression is thoracic (70%); lumbar compression occurs in 20% and cervical in 10%. In prostate carcinoma, compression involves one vertebral body in 26%, two in 42%, and three or more in 32%.

Pathogenesis

The vertebral column is the most common site of skeletal metastases. Several theories are proposed. First, bone marrow has a high concentration of factors that stimulate neoplastic growth. Second, the Batson vertebral venous plexus is a preferred site of drainage for pelvic, abdominal, and thoracic organs. Third, the lymphatic system, which anastomoses with the vertebral plexus, may also play a role. Concentration of blood vessels in the vertebral body exceeds other parts of the vertebra and makes it most vulnerable. Epidural cord compression usually results from direct extension of tumor from the vertebral column or metastases in the paravertebral spaces that grow through the neural foramina without affecting the bone. The mechanism of cord injury includes vertebral venous plexus compression with resultant cord edema and ischemia.

Clinical

Vertebral metastases may be completely asymptomatic. Pain is the first symptom in 95% of the patients with cord compression. Pain can be local or radicular and may be aggravated by movement, similar to arthritic pain. Several clinical features may help differentiate; pain from metastases may arise at any level, whereas degenerative arthritic pain is usually lumbar or cervical. Lying supine usually alleviates arthritic pain but aggravates metastatic pain. Limb weakness (76%), autonomic disturbances (57%), and sensory dysfunction (51%) are also observed. Urinary incontinence is a late symptom. Bandlike pain across the chest or abdomen may be misinterpreted as arising from abdominal viscera. The location of cord compression is usually indicated by a sensory level.

Diagnostic Evaluation

Plain spine radiographs reveal metastases in 85% of patients with cord compression; loss of vertebral pedicles is the first sign, but it occurs after there is extensive bone destruction. Radiographic abnormalities are common in patients with breast, lung, or prostate carcinoma but rare in patients with lymphoma. Prostate carcinoma produces osteoblastic lesions, whereas breast cancer leads to lytic ones. In patients with pain and abnormal radiographs, cord compression is documented on myelography in 86%, but in those with symptoms and normal radiographs, compression is found in 8%. Noncontrast MRI is the preferred test for epidural tumor. About 27% of patients with focal signs show multiple sites of compression, so MRI should include the entire spine to identify areas of unrecognized epidural tumor that might benefit from early irradiation. A diagnostic protocol has been proposed by Portenoy (1987). If the only symptom is pain, with no neurologic signs but radiographs are abnormal, many would irradiate the symptomatic vertebra without further imaging. If the patient has mild signs or symptoms, MRI or myelogram may be performed the next day; patients with severe or rapidly progressive symptoms must have an emergency MRI or myelogram.

Therapy

The most important aspects of management are preservation of neurologic function and alleviation of pain. Pain without cord compression may be treated with analgesics or radiation if analgesics are ineffective. Early recognition and treatment are crucial. Corticosteroids alleviate pain and improve the neurologic disorder. Many centers start dexamethasone at 4 mg four times a day, others give an intravenous bolus of 100 mg, followed by 24 mg four times a day, and a tapering schedule with the radiation.

A common radiation program is 3,000 to 4,000 cGy over 2 to 4 weeks. Radiation usually includes two vertebral bodies above and two below the lesion. In some studies, surgery and radiotherapy were not better than radiation alone. Posterior tumors are best approached by laminectomy, whereas anterior ones may require thoracotomy, vertebral body resection, and spinal stabilization. Surgery is considered in the following circumstances: cord compression and unknown primary tumor, worsening symptoms and signs referable to a previously irradiated level, spinal instability, neurologic deterioration despite radiotherapy and steroids, and radioresistant tumors. In patients with prostate cancer, the use of orchiectomy as the sole therapy to reduce the testosterone level, may lead to improvement. The most important prognostic factor is the neurologic status at the time of treatment: Up to 80% of ambulatory patients remained ambulatory, whereas only 50% of those with leg weakness and 10% of those with paralysis walked again. Pain can be relieved in 96% of patients treated with corticosteroids and radiation. Patients with compression fractures are less likely to have a favorable response to external radiotherapy, and early surgery should be considered. Survival depends mostly on control of the underlying malignancy.

GRANULOMAS

CNS granulomas may mimic metastatic or primary brain tumors and are discussed in [Chapter 24](#), [Chapter 25](#), and [Chapter 26](#). The lesions have histologic signs of chronic inflammation and are seen with sarcoidosis, syphilis, tuberculosis, fungi, or parasites.

Intracranial tuberculomas constitute one-third of all intracranial space-occupying lesions in developing countries but are rare in the United States and Europe, even in patients with acquired immunodeficiency syndrome and tuberculosis. Parenchymal disease can occur with or without meningitis. *Miliary pulmonary tuberculosis* commonly affects the brain; the patient may be asymptomatic despite multiple, small, contrast-enhancing lesions in the gray–white matter junction. Symptoms are related to location. Children favor the infratentorial compartment, whereas lesions in adults are mostly in the frontal and parietal lobes.

Pathologically, at first, the lesion is noncaseating. Eventually, a central zone of necrosis is surrounded by a capsule composed of epithelioid cells, multinucleated giant cells, collagen, and mononuclear inflammatory cells. Tuberculosis organisms are rarely seen. CT and MRI show lobular masses with irregular enhancement. A target sign is helpful in diagnosis. Thirty-four percent of the lesions are multiple, mainly at the corticomedullary junction. MRI features depend on the stage of the granuloma. An “en plaque” tuberculoma may mimic a meningeal neoplasm.

Tuberculous abscess is also rare. Compared with granulomas, it is larger, composed of pus and tubercle bacilli, accompanied by edema, and with a more rapid course. On CT, it may seem to be a pyogenic abscess. The walls are thin, and enhancement is smooth. Surgical treatment is considered if a lesion suspected of being a tuberculoma does not respond to antibiotic treatment.

Calvarial tuberculosis results from hematogenous or lymphatic dissemination or from direct extension from sinuses, nasal cavity, or orbit. Radiographically there is a single circumscribed calvarial defect. *Tuberculous otomastoiditis* causes otorrhea, facial paralysis, and multiple tympanic membrane perforations.

The first account of *spinal tuberculosis* was done by Sir Percival Pott in 1779, and the condition was named after him. Location is commonly the thoracolumbar junction, usually involving two adjoining vertebrae. Focal destruction of a vertebral body is the most common lesion, spreading to the intervertebral discs, epidural space, or paraspinal soft tissues. The route of infection is hematogenous, and the mycobacteria lodge in the vascular marrow. In children, disks may be affected without vertebral body disease. The course is indolent, with persistent pain, local tenderness, or limitation of mobility. Myelopathic signs may be seen if there is associated epidural infection or if bony fragments enter the spinal canal. About 40% of patients have paraparesis. Fever is seen late in the course. The erythrocyte sedimentation rate is high and skin tuberculosis tests are positive. CT-guided biopsy confirms the diagnosis. Spinal radiculomyelitis occurs if the exudates encompass the cord and spinal roots. Treatment consists of an antituberculosis regimen in addition to surgical drainage, removal of necrotic tissue, and decompression of the epidural spine or spinal fusion.

CHAPTER 62. SPINAL TUMORS

PAUL C. MCCORMICK, MICHAEL R. FETELL AND LEWIS P. ROWLAND

[Pathology](#)
[Frequency](#)
[Symptoms](#)
[Extramedullary Tumors](#)
[Spinal Metastases](#)
[Intramedullary Metastases](#)
[Primary Intramedullary Tumors](#)
[Intradural Tumors](#)
[Regional Syndromes](#)
[Diagnosis of Spinal Tumors](#)
[Course and Prognosis](#)
[Treatment of Primary Spinal Tumors](#)
[Suggested Readings](#)

Tumors of the spinal cord or nerve roots are similar to intracranial tumors in cellular type. They may arise from the parenchyma of the cord, nerve roots, meninges, intraspinal blood vessels, sympathetic nerves, or vertebrae. Metastases may arise from remote tumors.

Spinal tumors are divided by location into three groups: intramedullary, intradural, or extradural. Occasionally, an extradural tumor extends through an intervertebral foramen to be partially within and partially outside the spinal canal (dumbbell or hourglass tumors).

PATHOLOGY

The histologic characteristics ([Table 62.1](#)) of primary and secondary tumors are similar to those of intracranial tumors. Intramedullary tumors are rare, accounting for about 10% of all spinal tumors. In contrast, benign encapsulated tumors ([Fig. 62.1](#) and [Fig. 62.2](#)), meningiomas, and neurofibromas comprise about 65% of all primary spinal tumors. Intramedullary tumors are more common in children, and extramedullary tumors are more common in adults.

Type	Percent
Neurofibromas	29
Meningiomas	26
Ependymomas	13

TABLE 62.1. RELATIVE FREQUENCY OF VARIOUS TYPES OF SPINAL TUMOR

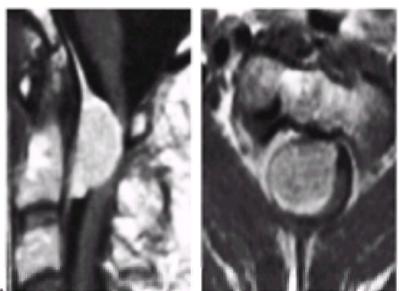

FIG. 62.1. Cervical meningeoma. **A:** T1-weighted contrast-enhanced sagittal magnetic resonance image demonstrates a large intradural mass at C1-2. **B:** Axial magnetic resonance image demonstrates the large size of this lesion, probably a meningioma. Despite marked spinal cord compression, the patient had no abnormality on neurologic examination.

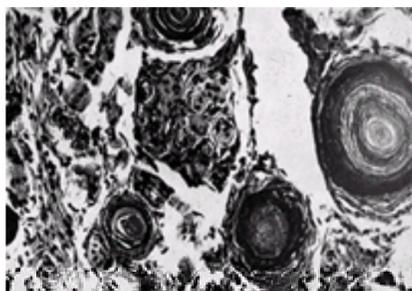

FIG. 62.2. Meningioma of the spinal cord with whorls.

The primary sites of metastatic tumors to the spine in order of frequency are lung, breast, and prostate. Other origins include gastrointestinal tract, lymphoma, melanoma, kidney, sarcoma, thyroid, and myeloma.

FREQUENCY

Spinal cord tumors are much less prevalent than intracranial tumors in a ratio of 1:4, but this varies by histology. The intracranial-to-spinal ratio of astrocytoma is 10:1, and the ratio for ependymomas varies from 3:1 to 20:1. Men and women are affected equally often, except that meningiomas are more common in women and ependymomas are more common in men. Spinal tumors occur predominantly in young or middle-aged adults and are less common in childhood or after age 60 ([Table 62.2](#)). Spinal tumors appear most often in the thoracic region, but if the relative lengths of the divisions of the spinal cord are considered, the distribution is relatively

equal. Ependymomas may be either intramedullary or extramedullary; at the conus, an ependymoma may be wholly or partially extramedullary.

Age (yr)	No. of cases	Percent
0-9	19	2
10-19	98	10
20-29	156	16
30-39	177	18
40-49	238	25
50-59	186	19
Over 60	101	10
Total	975	100

*Data compiled from the literature.

TABLE 62.2. AGE INCIDENCE OF SPINAL TUMORS OF ALL TYPES^a

SYMPTOMS

Extramedullary tumors cause symptoms by compressing nerve roots or spinal cord or by occluding the spinal blood vessels. The symptoms of intramedullary tumors result from direct interference with the intrinsic structures of the spinal cord from mass effect, edema, or development of syringomyelia. Descriptions of special syndromes follow.

EXTRAMEDULLARY TUMORS

These tumors may be either intradural or extradural. They usually involve a few cord segments and cause focal signs by compressing nerve roots, especially the dorsal roots. Extramedullary tumors may ultimately affect the spinal cord, with complete loss of function below the level of the lesion. The first symptoms are focal pain and paresthesias, arising from pressure on the dorsal nerve roots, and neurofibromas originate from these structures. This symptom pattern is soon followed by sensory loss, weakness, and muscular wasting in the distribution of the affected roots. Compression of the spinal cord first interrupts the functions of the pathways that lie at the periphery of the spinal cord. The early signs of cord compression include spastic weakness below the lesion; impairment of cutaneous and proprioceptive sensation below the lesion; impaired control of the bladder and, less often, the rectum; and increased tendon reflexes, Babinski signs, and loss of superficial abdominal reflexes. If untreated, this syndrome may lead to signs and symptoms of complete transection of spinal cord, with wasting and atrophy of muscles at the level of the root lesion and, below the lesion, paraplegia or quadriplegia in flexion.

The severity and distribution of weakness and sensory loss varies, depending in part on the location of the tumor in relation to the anterior, lateral, or posterior portion of the spinal cord. Eccentrically placed tumors may cause a typical Brown-Séquard syndrome: ipsilateral signs of posterior column and pyramidal tract dysfunction, with contralateral loss of pain and temperature due to involvement of the lateral spinothalamic tract. Usually, however, the Brown-Séquard features are incomplete.

Spinal vessels may be occluded by extradural tumors, particularly metastatic carcinoma, lymphoma, or abscess. When the arteries destined for the spinal cord are occluded, the resulting myelomalacia causes signs and symptoms similar to those of severe intradural compression and necrosis of the spinal cord. Occlusion of major components of the anterior spinal artery, however, results in segmental lower motor neuron signs at the appropriate level, bilateral loss of pain and temperature sensation, and upper motor neuron signs below the lesion. The posterior columns are generally spared.

SPINAL METASTASES

Epidural Spinal Cord Compression

Epidural spinal metastases can be considered a disorder of the vertebral column; the neurologic consequences result from extension of tumor into the spinal canal. Patients with primary malignant tumors now survive longer, and the incidence of epidural spinal cord compression has increased to about 5% to 10% of all cancer patients. Treatment of cord compression does not prolong survival but may relieve pain and may prevent neurologic disability.

Signs and symptoms of epidural spinal cord compression are easily overlooked in a patient with cancer who is often wracked by asthenia and diffuse pain. The physician, however, must respond to neck or back pain that is relentless and persists when the patient lies in bed, even if the pain is relieved by analgesics. Limb weakness, paresthesias in the distribution of a nerve root, and bowel or bladder dysfunction create a neurooncologic emergency that commands prompt evaluation and treatment. Rarely, the only manifestation of cord compression is a gait disorder, often due to sensory ataxia, without overt evidence of weakness or cutaneous sensory loss. It may even be difficult to demonstrate impaired proprioception. The ataxia may be caused by compression of spinocerebellar pathways. The tumor in more than 50% of cases of epidural cord compression arises from lung or breast; more than 80% of cases arise from primary tumors in lung, breast, gastrointestinal system, prostate, melanoma, or lymphoma.

These tumors spread to the epidural space by direct centripetal invasion from a paravertebral focus through a nerve root foramen, hematogenous metastasis to the vertebrae with extension from bone into the epidural space, or retrograde spread along the venous plexus of Batson. Hematogenous spread is the most common, and computed tomography (CT) shows lytic or blastic changes in 85% of patients. Osteoblastic changes are common with myeloma, prostate carcinoma, and Hodgkin disease and are occasionally seen with breast cancer. CT and magnetic resonance imaging (MRI) are sensitive techniques for the detection of spinal osseous metastases, and MRI has largely replaced myelography ([Fig. 62.3](#) and [Fig. 62.4](#)).

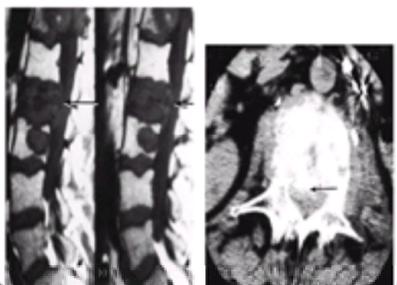

FIG. 62.3. A: Epidural spinal metastases. T1-weighted sagittal magnetic resonance image demonstrates multiple levels of spinal involvement from metastatic renal carcinoma. The L2 vertebra (*arrow*) is collapsed, and there is epidural extension of tumor and bone at this level. **B:** Axial computed tomography demonstrates the degree of bone destruction at the L2 level. Note the retropulsion of bone fragments into the epidural space (*arrow*).

FIG. 62.4. Epidural spinal metastases. T1-weighted sagittal magnetic resonance image demonstrates destruction and collapse of the T6 vertebra in a patient with multiple myeloma. In addition to spinal cord compression from epidural extension of the neoplasm, there is a kyphotic deformity of the spine, indicating instability. Note the hyperintense marrow signal in the bodies of T9 and T10, indicating additional metastatic deposits.

Treatment of Epidural Metastatic Disease

Treatment of epidural metastasis is palliative in nearly all patients. Management must be individually tailored to consider the patient's age, clinical state, extent of systemic disease, life expectancy, tumor pathology (if known), and extent of spinal lesions. The keys to successful management are timely diagnosis and prompt treatment. Persistent back or neck pain in a patient with known cancer is presumed to indicate metastatic spinal disease until proved otherwise. Emergency treatment of the patient with rapidly progressive paraparesis rarely reverses the neurologic signs. Loss of bowel or bladder function is an ominous prognostic sign and is usually irreversible. Among patients diagnosed and treated early (while they can still walk), 94% remain ambulatory until they die.

Radiation (3,000 cGy in 10 fractions of 300 cGy each) is the treatment of choice for most patients with spinal metastases. It is tolerated well even by patients who are seriously ill, and in most cases, palliation is achieved with relief of pain, local tumor control, and prevention or reversal of neurologic impairment. Indications for surgery include tumors such as melanoma and other radioresistant tumors, recurrent tumor at a site of prior radiation therapy, spinal instability, unknown tissue diagnosis, or rapid progression of neurologic disorder. Patients with advanced systemic disease are poor surgical candidates. The choice of operative approach is debated; some surgeons advocate an anterior approach over radiation therapy or posterior laminectomy. The attendant surgical risks of anterior decompression have to be considered.

INTRAMEDULLARY METASTASES

The most common tumors that cause intramedullary metastases are lung cancer or breast cancer ([Fig. 62.5](#)). Intramedullary metastases occur with advanced metastatic disease, and 61% of patients with intramedullary metastases have had multiple sites of cerebral or spinal lesions at autopsy. MRI is the preferred diagnostic method for detection of intramedullary metastases. Reversal or stabilization of neurologic signs depends on early diagnosis, but survival is poor; 80% of patients in one series died within 3 months of diagnosis.

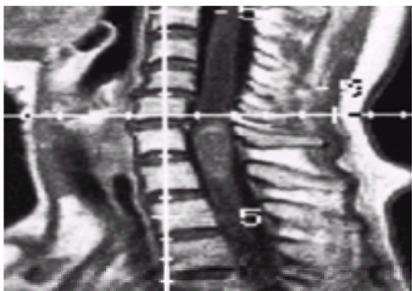

FIG. 62.5. Intramedullary metastasis. Sagittal T1-weighted contrast-enhanced magnetic resonance image shows a faintly contrast-enhancing tumor at C6-7 expanding the cervical cord in a patient with widely metastatic small cell lung cancer. Biopsy was not performed, and the tumor receded with radiation therapy.

PRIMARY INTRAMEDULLARY TUMORS

Primary intramedullary tumors usually extend over many segments, sometimes involving the whole length of the spinal cord. For this reason, the signs and symptoms of intramedullary tumors are more variable than those of extramedullary tumors ([Fig. 62.6](#)). If the tumor is restricted to one or two segments, the syndrome is similar to that of an extramedullary tumor. Commonly, however, the tumor involves several segments. Pain may be an early manifestation if the dorsal root entry zone is affected. Compression of the crossing pain fibers in the central cord may cause loss of pain and temperature only in the affected segments. As the tumor spreads peripherally, the spinothalamic tracts may be affected; in the thoracic and cervical areas, pain and temperature fibers from the sacral area lie near the external surface of the cord and may be spared (sacral sparing). Involvement of the central gray matter destroys the anterior horn cells, with local weakness and atrophy. However, pyramidal fibers may be spared. The clinical picture may be identical to that of syringomyelia.

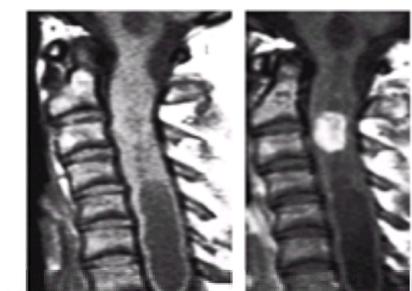

FIG. 62.6. Intramedullary astrocytoma. **A:** T1-weighted sagittal magnetic resonance image demonstrates a large cyst in the lower cervical spinal cord and a smaller cyst extending up into the medulla. The intervening spinal cord is slightly enlarged but demonstrates no signal abnormality. **B:** T1-weighted magnetic resonance image shows a contrast-enhancing intramedullary tumor at the C2-3 level. At operation, a well-circumscribed pilocytic astrocytoma was removed.

INTRADURAL TUMORS

Neurofibromas, *schwannomas*, and *meningiomas* are the most common primary intradural tumors of the spinal cord. On MRI after the administration of gadolinium, the lesions enhance brightly ([Fig. 62.7](#)). Meningiomas may be identified by the presence of a "dural tail," where the tumor attaches to the dura. *Leptomeningeal*

metastasis and *drop metastases* of intracranial tumors also involve the intradural space but typically appear as small nodules attached to the surface of the cord or cauda equina nerve roots (Fig. 62.8).

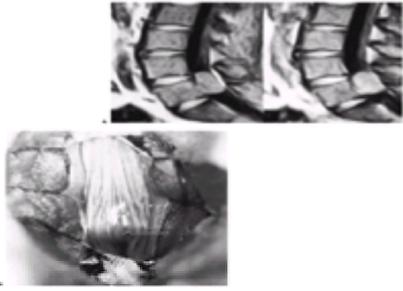

FIG. 62.7. Schwannoma. **A:** Gadolinium-enhanced T1-weighted sagittal magnetic resonance image demonstrates large intradural tumor at the L5 level. Differential diagnosis includes nerve sheath tumor, meningioma, filum terminale ependymoma, and intradural (“drop”) metastases. **B:** Intraoperative photograph demonstrates a large intradural schwannoma (*arrow*) that displaces the cauda equina dorsally.

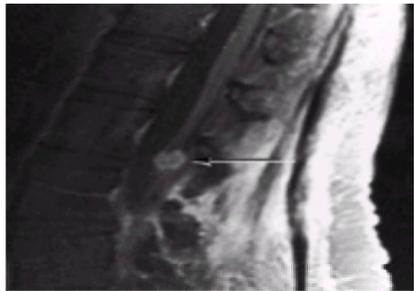

FIG. 62.8. “Drop metastases.” Sagittal T1-weighted contrast-enhanced magnetic resonance image shows an intradural module (*arrow*) of a fourth ventricular choroid plexus papilloma that has seeded the cauda equina.

REGIONAL SYNDROMES

Foramen Magnum Tumors

Tumors in the region of the foramen magnum may extend up into the posterior fossa or down into the cervical region. The syndrome is typified by signs and symptoms of dysfunction of the lower cranial nerves—primarily the eleventh, twelfth, and, rarely, the ninth and tenth. The most characteristic foramen magnum tumor, the ventrolateral meningioma, compresses the spinal cord at the cervicomedullary junction to cause posterior column signs: loss of position, vibratory, and light touch perception, more prominent in the arms than in the legs. Upper motor neuron signs are seen in all four limbs. There may be cutaneous sensory loss in distribution of C2 or the occiput, with posterior cranial headache and high cervical pain. Progression of sensory and motor symptoms may involve the limbs asymmetrically.

Cervical Tumors

Tumors of the upper cervical segments cause pain or paresthesias in the occipital or cervical region and stiff neck, with weakness and wasting of neck muscles. Below the lesion, there may be a spastic tetraplegia or hemiplegia. Cutaneous sensation may be affected below the lesion, and the descending trigeminal nucleus may be involved. Characteristic findings make it possible to localize the upper level of spinal tumors in the middle and lower cervical segments or T1 as follows:

C4: Paralysis of the diaphragm.

C5: Atrophy and paralysis of the deltoid, biceps, supinator longus, rhomboid, and spinati muscles. The upper arms hang limp at the side. The sensory level extends to the outer surface of the arm. The biceps and supinator reflexes are lost.

C6: Paralysis of triceps and wrist extensors. The forearm is held semiflexed and there is a partial wristdrop. The triceps reflex is lost. Sensory impairment extends to a line running down the middle of the arm slightly to the radial side.

C7: Paralysis of the flexors of the wrist and of the flexors and extensors of the fingers. Efforts to close the hands result in extension of the wrist and slight flexion of the fingers (preacher’s hand). The sensory level is similar to that of the sixth cervical segment but slightly more to the ulnar side of the arm.

C8: Atrophy and paralysis of the small muscles of the hand with resulting clawhand (*main-en-griffe*). *Horner syndrome*, unilateral or bilateral, results from lesions at this level and is characterized by the triad of ptosis, small pupil (miosis), and loss of sweating on the face. Sensory loss extends to the inner aspect of the arm and involves the fourth and fifth fingers and the ulnar aspect of the middle finger.

T1: Lesions rarely cause motor symptoms because the T1 nerve root normally provides little functional innervation of the small hand muscles.

Other signs of cervical tumors include nystagmus, which is attributed to involvement of the descending portion of the median longitudinal fasciculus. A Horner syndrome may be found with intramedullary lesions in any portion of the cervical cord if the descending sympathetic pathways are affected.

Thoracic Tumors

Clinical localization of tumors in the thoracic region of the cord is best made by the sensory level. It is not possible to determine the location of a lesion in the upper half of the thoracic cord by testing the strength of intercostal muscles. Lesions that affect the abdominal muscles below T10 but spare the upper ones can be localized by the Beevor sign: the umbilicus moves upward when the patient, lying in the supine position, attempts to flex the neck against resistance. Abdominal skin reflexes are absent below the lesion.

Lumbar Tumors

Lesions in the lumbar region can be localized by the level of the sensory loss and motor weakness. Tumors that compress only the L1 and L2 segments cause loss of the cremasteric reflexes. The abdominal reflexes are preserved, as are the knee and ankle jerks.

If the tumor affects the L3 and L4 segments and does not involve the cauda equina, the signs are weakness of the quadriceps, loss of the patellar reflexes, and hyperactive Achilles reflexes. More commonly, lesions at this level also involve the cauda equina to cause flaccid paralysis of the legs with loss of knee and ankle reflexes. If both the spinal cord and cauda equina are affected, there may be spastic paralysis of one leg with an overactive ankle reflex on that side and flaccid

paralysis with loss of reflexes on the other side.

Tumors of the Conus and Cauda Equina

The first symptom of a tumor that involves the conus or cauda equina is pain in the back, rectal area, or both lower legs, often leading to the diagnosis of sciatica. Loss of bladder function and impotence are seen early. As the tumor grows, there may be flaccid paralysis of the legs, with atrophy of leg muscles and foot drop. Fasciculation may be evident. Sensory loss may affect the perianal or saddle area and the remaining sacral and lumbar dermatomes. This loss may be slight or so severe that a trophic ulcer develops over the lumbosacral region, buttocks, hips, or heels.

Signs of raised intracranial pressure may be seen with ependymomas of this region if the cerebrospinal fluid (CSF) protein content is over 100 mg/dL.

DIAGNOSIS OF SPINAL TUMORS

Tumors compressing the spinal cord or the cauda equina cause radicular pain and the slow evolution of signs of an incomplete transverse lesion of the cord or signs of compression of the cauda equina. Extradural tumors that do not compress the spinal cord may obstruct the blood supply to the cord; if this occurs, the symptoms are often of sudden onset, and the tumor is either metastatic or a granuloma of the Hodgkin type. In a patient with Von Recklinghausen disease, the skin lesions may suggest the presence of a neurofibroma, glioma, or ependymoma.

The diagnosis of an intraspinal tumor can be established before operation with absolute certainty by CT, MRI, or myelography. Vascular malformations or vascular tumors may be visualized by spinal angiography. Examination of the CSF may also be helpful.

Radiography

CT and MRI have largely replaced plain films but are not available everywhere. In about 15% of spinal neoplasms, one or more of the following abnormalities are seen in plain radiographs.

1. Localized destruction of the vertebrae is manifested by scalloping of the posterior margin of the vertebral body or lucency of a portion of the vertebra or pedicle.
2. Changes occur in the contour of or separation of the pedicles (the interpediculate distance can be measured and compared with normal values). Localized enlargement of foramina is seen in the dumbbell neurofibroma. Localized enlargement of the spinal canal is usually diagnostic of an intraspinal tumor, but enlargement of many segments may be a developmental anomaly.
3. Paraspinal tissues are distorted by tumors (frequently neurofibromas) that extend through the intervertebral foramen or by tumors that originate in the paraspinal structures.
4. Proliferation of bone, which is rare except in osteomas and sarcomas, is also occasionally seen in hemangiomas of bone and meninges.
5. Calcium deposits are occasionally present in meningiomas or congenital tumors.

Diagnostic Imaging

MRI has largely supplanted myelography. In patients with partial spinal block, myelography may alter CSF pressure relationships, causing complete spinal block and neurologic deterioration. MRI is the most useful test for evaluating spinal tumors. The vertebral bodies, spinal canal, and spinal cord itself are clearly delineated. Injection of gadolinium assists because most spinal neoplasms display contrast enhancement. When a metastatic tumor is demonstrated, it is advisable to image the entire cord because more than one lesion may be present.

CT is more limited than MRI. Without the intrathecal instillation of a contrast agent, CT cannot be relied on to demonstrate the soft tissue changes of intraspinal tumors. However, the extraspinal aspects, such as metastatic cancer, may be identified. With intrathecal injection of contrast agents, intraspinal tumors are usually seen. The contrast material may leach into the cavity to establish the diagnosis of syringomyelia or cystic tumor.

Cerebrospinal Fluid

When there is a complete subarachnoid block, the CSF is xanthochromic as a result of the high protein content. It may be only slightly yellow or colorless if the subarachnoid block is incomplete. The cell count is usually normal, but a slight pleocytosis is found in about 30% of patients. Cell counts between 25 and 100/mm³ are found in about 15% of the patients. The protein content is increased in more than 95%. Values over 100 mg/dL are present in 60% of the patients and values over 1,000 mg/dL are present in 5% and may, in rare cases, lead to communicating hydrocephalus. The glucose content is normal unless there is meningeal spread. Cytologic evaluation of the CSF is useful when malignant tumors are suspected.

Differential Diagnosis

Spinal tumors must be differentiated from other disorders of the spinal cord, including transverse myelitis, multiple sclerosis, syringomyelia, combined system disease, syphilis, amyotrophic lateral sclerosis, anomalies of the cervical spine and base of the skull, spondylosis, adhesive arachnoiditis, radiculitis of the cauda equina, hypertrophic arthritis, ruptured intervertebral discs, and vascular anomalies. *Epidural lipomatosis* is a complication of prolonged steroid therapy but sometimes occurs without apparent cause; the fat accumulations act as an intraspinal mass lesion, causing low back pain and compression of the spinal cord or cauda equina.

Multiple sclerosis, with a complete or incomplete transverse lesion of the cord, can usually be differentiated from spinal cord tumors by the remitting course, signs and symptoms or more than one lesion, evoked potential studies, cranial MRI, and presence of CSF oligoclonal bands. Acute transverse myelitis may occasionally enlarge the cord to simulate an intramedullary tumor.

The differential diagnosis between syringomyelia and intramedullary tumors is complicated because intramedullary cysts are commonly associated with these tumors. Extradural tumors in the cervical region may give rise to localized pains and muscular atrophy in conjunction with a Brown-Séquard syndrome, producing a clinical picture similar to that of syringomyelia. The diagnosis of syringomyelia is likely when trophic disturbances are present. The differential diagnosis can often be made by contrast-enhanced MRI that reveals a tumor nodule ([Fig. 62.6](#)).

The combination of atrophy of hand muscles and spastic weakness in the legs in amyotrophic lateral sclerosis may suggest the diagnosis of a cervical cord tumor. Tumor is excluded by the lack of paresthesias and normal sensation on examination and the presence of fasciculation or atrophy in leg muscles.

Cervical spondylosis, with or without rupture of the intervertebral disks, may cause symptoms and signs of root irritation and compression of the spinal cord. The osteoarthritis can be diagnosed by findings in plain radiographs, but this is so common in asymptomatic people that MRI may be necessary to determine whether there is spondylotic myelopathy or an extradural tumor. Even MRI may show spondylosis in asymptomatic people.

Anomalies in the cervical region or at the base of the skull, such as *platybasia* or *Klippel-Feil syndrome*, are diagnosed by CT or MRI. Occasionally, arachnoiditis may interfere with the circulation in the cord, causing signs and symptoms of a transverse lesion. The CSF protein content is elevated. Diagnosis is made by complete or partial arrest of the contrast column on myelography or by fragmentation of the material at the site of the lesion. Separation of the adhesions and removal of the thickened arachnoid by surgery have been of little benefit; steroid therapy is no better.

COURSE AND PROGNOSIS

Benign tumors of the spinal cord are characterized by slow progression for years. If a neurofibroma arises from a dorsal root, there may be years of radicular pain before the tumor is evident from other manifestations of growth. Intramedullary tumors are generally benign and slow growing; they may attain enormous size (over the course of 6 to 8 years) before they are discovered.

Conversely, the sudden onset of a severe neurologic disorder, with or without pain, is usually indicative of a malignant extradural tumor, such as metastatic carcinoma

or lymphoma.

TREATMENT OF PRIMARY SPINAL TUMORS

Once the diagnosis of an intraspinal tumor has been made, the treatment is surgical removal of the tumor whenever possible. When the neurologic disorder is severe or rapidly progressing, emergency surgery is indicated. With microneurosurgery, the best results are obtained when the signs and symptoms are due solely to compression of the spinal cord by a meningioma, neurofibroma, or other benign encapsulated tumor. Some of these tumors, especially meningiomas, may lie anterior to the spinal cord and require the most delicate expertise of the neurosurgeon. Function may be completely restored even when severe spastic weakness has been present for years. The postoperative results, however, are often predicated on the severity of preoperative neurologic disability, which is a strong point in favor of early diagnosis and surgery for these tumors. Radiotherapy is not indicated for most intradural extramedullary tumors, even when removal has been incomplete, because these tumors are usually benign.

The most common intramedullary tumors are ependymomas and astrocytomas. In almost all ependymomas, the tumor can be resected by myelotomy and microsurgery (Fig. 62.9). Radiotherapy is not indicated after total removal and is rarely indicated after partial removal; the patient should be observed for recurrence. Additional operative procedures should be considered if they are indicated. Perhaps half of all intramedullary astrocytomas are resectable by microsurgery; again, postoperative radiotherapy is not indicated. When radiotherapy is given after incomplete removal of an astrocytoma, the results are discouraging. In the uncommon presence of other intramedullary tumors, such as hemangioblastomas, teratomas, or dermoids, complete removal without adjuvant radiotherapy is the rule.

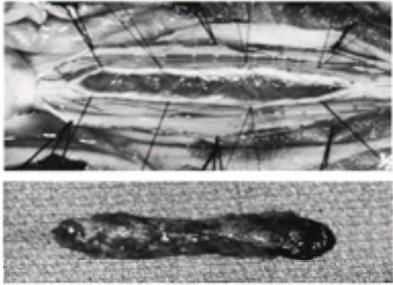

FIG. 62.9. Intradural ependymoma. **A:** Operative photograph. Myelotomy exposes the dorsal surface of the tumor. Note the clear demarcation of the tumor from the surrounding spinal cord. **B:** Operative photograph of the tumor specimen that has been completely removed.

After radical and extensive surgery for these tumors, spinal deformities (which may have been present preoperatively) may appear or increase, requiring fixation. These deformities, if allowed to progress, may in turn create neurologic syndromes due to spinal cord compression. This condition is especially pertinent in children. Some surgeons have advocated replacement of the lamina after definitive surgery rather than the standard laminectomy. The additional use of radiotherapy for intraspinal tumors in children may affect the growth of the spine, leading to or increasing preexisting deformities of the spine.

EPIDEMIOLOGY

Head injury is a modern scourge of industrialized society. It is a major cause of death, especially in young adults, and a major cause of disability. The costs in human misery and dollars are exceeded by few other conditions.

More than 2 million patients with head injuries are seen annually in U.S. emergency rooms, and 25% of these patients are hospitalized. Almost 10% of all deaths in the United States are caused by injury, and about half of traumatic deaths involve the brain. In the United States, a head injury occurs every 7 seconds and a death every 5 minutes. About 200,000 people are killed or permanently disabled annually as a result.

Brain injuries occur at all ages, but the peak is in young adults between the ages of 15 and 24. Head injury is the leading cause of death among people under the age of 24 years. Men are affected three or four times as often as women. The major causes of brain injury differ in different parts of the United States; in all areas, motor vehicle accidents are prominent, and in metropolitan areas, personal violence is particularly prevalent. Between 1979 and 1992, firearms surpassed vehicular trauma as the most common cause of fatal brain injury.

PATHOLOGY AND PATHOPHYSIOLOGY OF CRANIOCEREBRAL TRAUMA

Skull Fractures

Skull fractures can be divided into linear, depressed, or comminuted types. If the scalp is lacerated over the fracture, it is considered an open or *compound fracture*. Skull fractures are important markers of potentially serious injury but rarely cause problems by themselves; prognosis depends more on the nature and severity of injury to the brain than on the severity of injury to the skull.

About 80% of fractures are linear. They occur most commonly in the temporoparietal region, where the skull is thinnest. Detection of a linear fracture often raises the suspicion of serious brain injury, but computed tomography (CT) in most patients is otherwise normal. Nondisplaced linear skull fractures generally do not require surgical intervention and can be managed conservatively.

In *depressed fracture* of the skull, one or more fragments of bone are displaced inward, compressing the underlying brain. In comminuted fracture there are multiple shattered bone fragments, which may or may not be displaced. In 85% of cases, depressed fractures are open (or compound) and liable to become infected or leak cerebrospinal fluid (CSF). Even when closed, most depressed or comminuted fractures require surgical exploration for debridement, elevation of bone fragments, and repair of dural lacerations. The underlying brain is injured in many cases. In some patients, depressed skull fractures are associated with tearing, compression, or thrombosis of underlying venous dural sinuses.

Basilar skull fractures may be linear, depressed, or comminuted. They are frequently missed by plain skull x-rays and are best identified by CT with "bone windows." There may be associated cranial nerve injury or a dural tear adjacent to the fracture site, which can lead to delayed meningitis if bacteria enter the subarachnoid space. Signs that lead the physician to suspect a fracture of the petrous portion of the temporal bone include hemotympanum or tympanic perforation, hearing loss, CSF otorrhea, peripheral facial nerve weakness, or ecchymosis of the scalp overlying the mastoid process (Battle sign). Anosmia, bilateral periorbital ecchymosis, and CSF rhinorrhea suggest possible fracture of the sphenoid, frontal, or ethmoid bones.

Cerebral Concussion and Axonal Shearing Injury

Loss of consciousness at the moment of impact is caused by acceleration-deceleration movements of the head, which result in the stretching and shearing of axons. When the alteration of consciousness is brief (less than 6 hours), the term *concussion* is used. These patients may be completely unconscious or remain awake but "dazed"; most recover within seconds to minutes (rather than hours) and have retrograde and anterograde amnesia surrounding the event.

The mechanism by which concussion leads to loss of consciousness is believed to be transient functional disruption of the reticular activating system caused by rotational forces on the upper brainstem. Experimentally, violent head rotation can produce concussion without impact to the head. Most patients with concussion have normal CT or magnetic resonance (MR) findings, because concussion results from physiologic, rather than structural, injury to the brain. Only 5% of patients who have sustained a concussion and are otherwise intact have an intracranial hemorrhage on CT.

The term *diffuse axonal injury* (DAI) is applied to traumatic coma lasting more than 6 hours. In these cases, when no other cause of coma is identified by CT or MR imaging (MRI), it is presumed that widespread microscopic and macroscopic axonal shearing injury has occurred. Coma of 6 to 24 hours in duration is deemed mild DAI; coma lasting more than 24 hours is referred to as moderate or severe DAI, depending on the absence or presence of brainstem signs such as decorticate or decerebrate posturing (Table 63.1). Autonomic dysfunction (e.g., hypertension, hyperhidrosis, hyperpyrexia) is common in patients with acute severe DAI and may reflect brainstem or hypothalamic injury. Patients may remain unconscious for days, months, or years, and those who recover may be left with severe cognitive and motor impairment, including spasticity and ataxia. DAI is considered the single most important cause of persistent disability after traumatic brain damage.

	Mild concussion	Cerebral concussion	Diffuse axonal injury		
			Mild	Moderate	Severe
Loss of consciousness	None	Immediate	Immediate	Immediate	Immediate
Length of unconsciousness	None	<6hr	6-24	>24hr	Days-weeks
Decerebrate posturing	None	None	Rare	Occasionally	Present
Posttraumatic amnesia	Minutes	Minutes-hours	Hours	Days	Weeks
Memory deficit	None	Mild	Mild-moderate	Moderate-severe	Severe
Motor deficits	None	None	None	Mild	Severe
Outcome at 3 months (%)					
Good recovery	100	95	63	38	15
Moderate deficit	0	5	15	21	15
Severe deficit	0	0	6	12	16
Vegetative	0	0	1	5	7
Death	0	0	15	24	50

Adapted from Goodwin TA. Cerebral concussion and diffuse brain injuries. In: Cooper PR, ed. *Head Injury*. 3rd ed. Baltimore: Williams & Wilkins, 1981:40.

TABLE 63.1. CLINICAL CHARACTERISTICS AND OUTCOME OF DIFFUSE BRAIN INJURIES

Axonal shearing injury tends to be most severe in specific brain regions that are anatomically predisposed to maximal stress from rotational forces. At the time of injury, microscopic damage occurs diffusely, as manifest by axonal retraction bulbs throughout the white matter of the cerebral hemispheres. Macroscopic tissue tears, best visualized by MRI, tend to occur in midline structures, including the dorsolateral midbrain and pons, posterior corpus callosum, parasagittal white matter, periventricular regions, and internal capsule. Prolonged loss of consciousness from DAI tends to be associated with bilateral asymmetric focal lesions of the midbrain tegmentum, a region densely populated with reticular activating system neurons. Small hemorrhages, known as “gliding contusions,” are sometimes associated with focal shearing lesions.

Axonal shearing is thought to initiate a dynamic sequence of pathologic events that evolve over days to weeks. Initially, injury causes physical transection of some neurons and internal axonal damage to many others. In both cases, the process of axoplasmic transport continues, and materials flow from the cell body to the site of damage. These materials accumulate and can lead to secondary axonal transection with formation of a “retraction ball” from 12 hours to several days after the injury. Membrane channels may open to admit toxic levels of calcium. If the patient survives, there may be later evidence of Wallerian degeneration and gliosis.

Brain Swelling and Cerebral Edema

Brain swelling after head injury is a poorly understood phenomenon that can result from several different mechanisms. Posttraumatic brain swelling may result from *cerebral edema* (defined as an increase in the content of extravascular brain water), an increase in *cerebral blood volume* due to abnormal vasodilatation, or both. Cerebral edema can be further classified as cytotoxic, vasogenic, or interstitial (see [Chapter 49](#)). The swelling may be diffuse or focal, adjacent to a parenchymal or extradural hemorrhage.

Brain swelling can follow any type of head injury. Curiously, the magnitude of swelling does not always correlate well with the severity of injury. In some cases, particularly in young people, severe diffuse brain swelling, which may be fatal, occurs minutes to hours after a minor concussion. Abnormal dilation of the cerebral blood vessels is thought to lead to increased cerebral blood volume, hyperperfusion, and increased vascular permeability, resulting in secondary leakage of plasma and vasogenic cerebral edema. Cerebral blood flow studies indicate that some degree of hyperemia occurs in nearly all patients 1 to 3 days after severe head injury. Severe brain swelling may be related to this phenomenon or may result from damage to cerebral vasomotor regulatory centers in the brainstem.

Parenchymal Contusion and Hemorrhage

Cerebral *contusions* are focal parenchymal hemorrhages that result from “scraping” and “bruising” of the brain as it moves across the inner surface of the skull. The inferior frontal and temporal lobes, where brain tissue comes in contact with irregular protuberances at the base of the skull, are the most common sites of traumatic contusion ([Fig. 63.1](#)). Tearing of the meninges or cerebral tissue, usually a result of cuts from the sharp edges of depressed skull fragments, is called a *laceration*.

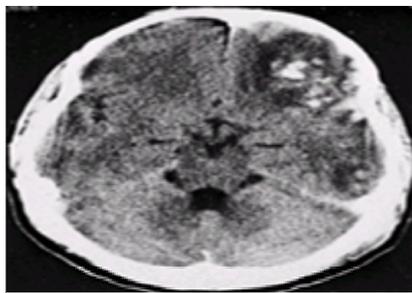

FIG. 63.1. Traumatic contusions. Axial noncontrast view demonstrates areas of contusion with small focal hemorrhages involving the lower poles of the left frontal and temporal lobes adjacent to the rough cranial vault. (Courtesy of Drs. S.K. Hilal, J.A. Bello, and T.L. Chi.)

Contusions may occur at the site of a skull fracture but more often occur without a fracture and with the overlying pia and arachnoid left intact. In most patients, contusions are small and multiple. With lateral forces, contusions can occur at the site of the blow to the head (“coup lesions”) or at the opposite pole as the brain impacts on the inner table of the skull (“contrecoup lesions”). Contusions frequently enlarge over 12 to 24 hours; in some cases, contusions develop 1 or more days after injury.

When rotational forces lead to tearing of a small- or medium-sized vessel within the parenchyma, an intracerebral *hematoma* may occur ([Fig. 63.2](#)). Hematomas are focal collections of blood clot that displace the brain, in contrast to contusions, which resemble bruised and bloodied brain tissue ([Fig. 63.3](#)). Most parenchymal hematomas are located in the deep white matter, in contrast to contusions, which tend to be cortical.

FIG. 63.2. Traumatic intracerebral hemorrhage, frontal lobe. Axial noncontrast computed tomography demonstrates left frontal lobe density (hemorrhage), surrounding lucency (edema), and mass effect (sulcal and ventricular effacement). (Courtesy of Drs. S.K. Hilal and J.A. Bello.)

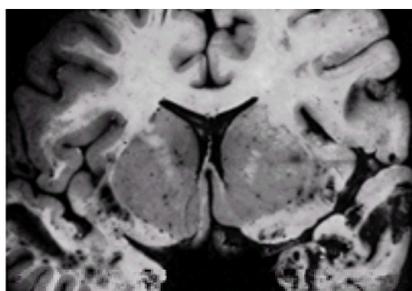

FIG. 63.3. Pathologic specimen demonstrating traumatic contusions in the temporal lobes.

If there is no DAI, brain swelling, or secondary hemorrhage, recovery from one or more small contusions may be excellent. Healed contusions are often found at autopsy of people with no clinical evidence of permanent brain damage. Large parenchymal hematomas with mass effect may require surgical evacuation.

Subdural Hematoma

Subdural hematomas usually arise from a venous source, with blood filling the potential space between the dural and arachnoid membranes. In most cases, the bleeding is caused by movements of the brain within the skull, which can lead to stretching and tearing of veins that drain from the surface of the brain to the dural sinuses. Less often, the source of the hematoma is a small pial artery.

Most subdural hematomas are located over the lateral cerebral convexities, but subdural blood can also collect along the medial surface of the hemisphere, between the tentorium and occipital lobe, between the temporal lobe and the base of the skull, or in the posterior fossa. CT usually reveals a high-density crescentic collection across the entire hemispheric convexity ([Fig. 63.4](#)). Elderly or alcoholic patients with cerebral atrophy are particularly prone to subdural bleeding; in these patients, large hematomas can result from trivial impact or even from pure acceleration-deceleration injuries such as whiplash.

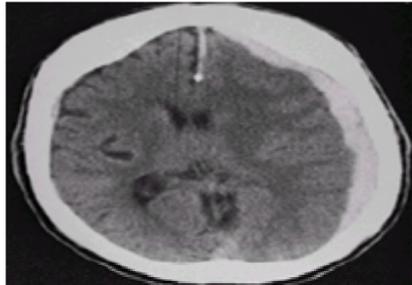

FIG. 63.4. Acute subdural hematoma. Noncontrast axial computed tomography demonstrates a hyperdense, crescent-shaped, extraaxial collection showing mass effect (sulcal and ventricular effacement) and midline shift from left to right. (Courtesy of Drs. J.A. Bello and S.K. Hilal.)

Acute subdural hematoma, by definition, is symptomatic within 72 hours of injury, but most patients have neurologic symptoms from the moment of impact. They can occur after any type of head injury but seem to be less common after vehicular trauma and relatively more common after falls or assaults. Half of patients with an acute subdural hematoma lose consciousness at the time of injury; 25% are in coma when they arrive at the hospital, and half of those who awaken lose consciousness for a second time after a "lucid interval" of minutes to hours, as the subdural hematoma grows in size. Hemiparesis and pupillary abnormalities are the most common focal neurologic signs; each occur in one-half to two-thirds of patients; the usual picture is ipsilateral pupillary dilation and contralateral hemiparesis. However, so-called false localizing signs are common with acute subdural hematoma, because uncal herniation can lead to compression of the contralateral cerebral peduncle or third cranial nerve against the tentorial edge (*Kernohan notch*).

Chronic subdural hematoma becomes symptomatic after 21 days or later. It is more likely to occur after age 50. In 25% to 50% of cases, there is no recognized head trauma. Almost half have a history of alcoholism or epilepsy and the trauma may have been forgotten. Other risk factors for chronic subdural hematoma include shunts and bleeding disorders, including anticoagulant medication.

In most cases of chronic subdural hematoma, the bleeding results from trivial trauma with little or no brain compression because of coexisting cerebral atrophy. After 1 week, fibroblasts on the inner surface of the dura form a thick outer membrane, and after 2 weeks a thin inner membrane develops, resulting in encapsulation of the clot, which begins to liquify. Enlargement of the hematoma may then result from recurrent bleeding ("acute-on-chronic" subdural hematoma) or because of osmotic effects related to a high protein content of the fluid. Symptoms may be restricted to altered mental status, a syndrome sometimes mistaken for dementia. CT typically shows an isodense or hypodense crescent-shaped mass that deforms the surface of the brain, and the membranes may enhance with intravenous contrast ([Fig. 63.5](#)). Long-standing chronic subdural hematomas eventually liquify and form a *hygroma*, and, in some cases, the membranes may calcify.

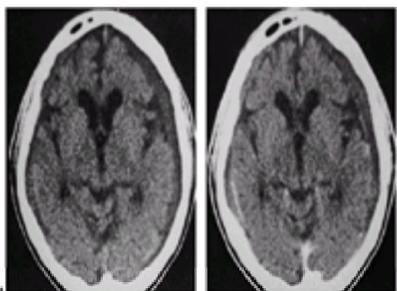

FIG. 63.5. Bilateral chronic subdural hematoma. **A:** Noncontrast axial computed tomography shows bilateral isodense extraaxial collections, larger on the left. **B:** These are better demonstrated on the postcontrast scan, in which enhancing membranes, typical of the subacute phase, can be seen. (Courtesy of Drs. J.A. Bello and S.K. Hilal.)

Acute and chronic subdural hematoma with significant mass effect should be evacuated. Reoperation for acute subdural hematomas is needed in about 15%. Small lesions, however, need not be treated surgically, and there is room for decision making, depending on the clinical condition of the patient.

Epidural Hematoma

Epidural hematoma is a rare complication of head injury. It occurs in less than 1% of all cases but is found in 5% to 15% of autopsy series, attesting to the potential seriousness of this complication.

Bleeding into the epidural space is generally caused by a tear in the wall of one of the meningeal arteries, usually the middle meningeal artery, but in 15% of patients the bleeding is from one of the dural sinuses. Seventy-five percent are associated with a skull fracture. The dura is separated from the skull by the extravasated blood, and the size of the clot increases until the ruptured vessel is compressed or occluded by the hematoma.

Most epidural hematomas are located over the convexity of the hemisphere in the middle cranial fossa, but occasionally the hemorrhage may be confined to the anterior fossa, possibly as a result of tearing of an anterior meningeal artery. Extradural hemorrhage in the posterior fossa may occur when the torcula Herophili is torn. In most cases, the hematoma is ipsilateral to the site of impact.

Epidural hematoma is primarily a problem of young adults; it is rarely seen in the elderly because the dura becomes increasingly adherent to the skull with age. The clinical course in one-third of patients proceeds from an immediate loss of consciousness due to concussion, to a lucid interval, and then a relapse into coma with hemiplegia as the epidural hematoma expands. The ipsilateral pupil becomes fixed and dilated because the third cranial nerve is compressed by the hippocampal

gyrus as it herniates over the free edge of the tentorium; the pupillary change signals impending brainstem compression (Fig. 63.6). As with acute subdural hematoma, false localizing signs may occur. The presence of cerebellar signs, nuchal rigidity, and drowsiness, together with a fracture of the occipital bone, should lead to the suspicion of a clot in the posterior fossa.

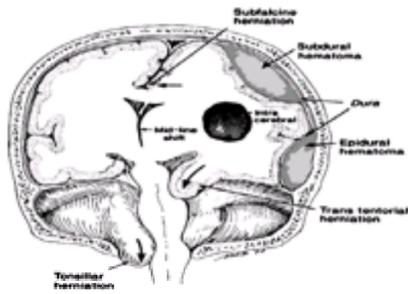

FIG. 63.6. Patterns of traumatic intracranial hemorrhage and brain herniation. [From White RJ, Likavei MJ, 1992.]

Epidural blood takes on a “bulging” convex pattern on CT (Fig. 63.7) because the collection is limited by firm attachments of the dura to the cranial sutures. Progression to herniation and death can occur rapidly because the bleeding is arterial. The mortality rate approaches 100% in untreated patients and ranges from 5% to 30% in treated patients. As the interval between injury and surgical intervention decreases, survival improves. If there is little coexisting brain damage, functional recovery may be excellent.

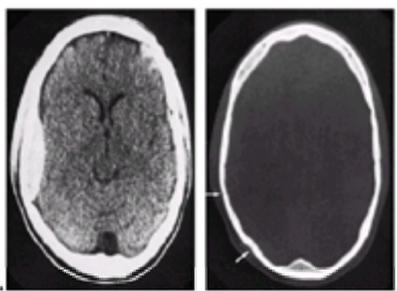

FIG. 63.7. A: Epidural hematoma is evident on computed tomography (CT). B: CT with bone windows shows two adjacent fractures (arrows); the anterior fracture is at the site of the groove for the middle meningeal artery.

Subarachnoid Hemorrhage

Some extravasation of blood into the subarachnoid spaces is to be expected in any head injury. In most cases, subarachnoid blood is detected only by CSF examination and is of little clinical importance. With more serious injuries, when larger vessels traversing the subarachnoid space are torn, focal or diffuse *subarachnoid hemorrhage* can be detected by CT. In these cases, blood is often distributed over the convexities; in contrast, aneurysmal bleeding results in collections of blood that are restricted to the basal cisterns. Although a large amount of subarachnoid blood is a poor prognostic sign, delayed complications of aneurysmal subarachnoid hemorrhage, such as hydrocephalus and ischemia from vasospasm, are rare after traumatic subarachnoid hemorrhage.

INITIAL ASSESSMENT AND STABILIZATION

On admission to the emergency room, resuscitation measures, history taking, and examination should begin simultaneously. The immediate goals of management are to assess and stabilize the airway, breathing, and circulation; to judge the severity of the head injury as low, moderate, or high risk; to rule out a fracture of the cervical spine; and to identify any extracranial injuries. All moderate- and high-risk patients require a CT to rule out a fracture or intracranial bleeding.

Hypoxia and *hypotension* can have devastating effects in head-injured patients. If the patient is hypoxic or in respiratory distress, endotracheal intubation is performed, ensuring that the spine remains immobilized. Hypotension should be corrected with intravenous boluses of isotonic fluids such as normal saline or lactated Ringer solution, blood transfusions, or pressors. Systolic blood pressure during the stabilization phase should be maintained above 90 mm Hg to ensure adequate cerebral blood flow. If the patient is hypotensive, bleeding into the abdomen, thorax, retroperitoneal space, or tissues surrounding a long bone fracture should be excluded. Hypotension may also reflect *spinal shock* related to a coexisting spinal cord injury (see [Chapter 64](#)). Hypertension associated with a wide pulse pressure and bradycardia (Cushing reflex) may reflect increased intracranial pressure (ICP) or focal brainstem injury.

A baseline neurologic evaluation should be performed immediately, while airway, breathing, and circulation are assessed. Injuries can be ranked as low, moderate, or high risk according to risk factors and a rapid initial neurologic assessment ([Table 63.2](#)). The Glasgow Coma Scale ([Table 63.3](#)) is based on eye opening and the patient’s best verbal and motor responses. It is widely used as a semiquantitative clinical measure of the severity of brain injury; it also provides a guide to prognosis ([Table 63.4](#)).

Risk category	Characteristics
Mild	Normal neurologic examination No concussion No drug or alcohol intoxication May complain of headache and dizziness May have scalp abrasion, laceration, or hematoma Absence of moderate or severe injury criteria
Moderate	Glasgow coma score of 9–14 (confused, lethargic, stuporous) Concussion Posttraumatic amnesia Vomiting Seizure Signs of possible basilar or depressed skull fracture or serious facial injury Alcohol or drug intoxication Unreliable or no history of injury Age <2 years, or possible child abuse
Severe	Glasgow coma scale score of 3–8 (comatose) Progressive decline in level of consciousness (“talked and deteriorated”) Focal neurologic signs Penetrating skull injury or palpable depressed skull fracture

Skull fracture	75-100

TABLE 63.4. ESTIMATED MORTALITY BASED ON VARIOUS FEATURES OF HEAD INJURY

Except for asymptomatic patients in the low-risk group, all should have CT. In all patients, a lateral cervical spine x-ray should be performed to rule out an unstable fracture. Before a cervical collar can be removed, the cervical spine must be cleared completely from C1 to C7.

Even before CT is performed, patients who are comatose (Glasgow Coma Scale Score ≤8) or who show clinical signs of herniation require emergency measures to reduce ICP, including head elevation, hyperventilation, and mannitol ([Table 63.5](#)).

1. Elevate head of bed 15-30 degrees
2. Normal saline (0.9%) at 80-100mL/hr (avoid hypotonic fluids)
3. Intubate and hyperventilate (target Pco₂ = 28-32 mm Hg)
4. Mannitol 20% 1-1.5 g/kg via rapid i.v. infusion
5. Foley catheter
6. Neurosurgical consultation

ICP, intracranial pressure.

TABLE 63.5. EMERGENCY MEASURES FOR ICP REDUCTION IN AN UNMONITORED PATIENT WITH CLINICAL SIGNS OF HERNIATION

DIAGNOSIS

History

The circumstances of the accident and the clinical condition of the patient before admission to the emergency room should be ascertained from emergency medical services records, the patient (if possible), and eyewitnesses. The force and location of head impact should be determined as precisely as possible. Specific inquiry should be made regarding concussion; because patients are amnesic during concussion, only an eyewitness can accurately gauge the duration of loss of consciousness.

Patients who have “talked and deteriorated” should be assumed to have an expanding intracranial hematoma until proven otherwise. Reports of headache, nausea, vomiting, confusion, or seizure activity must be noted. A medical history, including medications and drug and alcohol use, should be obtained. Recent drug and alcohol use occurs in a large percentage of traumapatients, and intoxication can confound assessments of mental status.

Examination

After the initial neurologic assessment, a more detailed physical and neurologic examination should be performed. The skull should be palpated for fractures, hematomas, and lacerations. A “step off,” or palpable bony shelf, is presumed to represent a depressed skull fracture. The patient should be thoroughly examined for external signs of trauma to the neck, chest, back, abdomen, and limbs. A bloody discharge from the nose or ear may indicate leakage of CSF; bloody CSF can be differentiated from blood by a positive halo test (a “halo” of CSF forms around the blood when dropped on a white cloth sheet). If there is no admixture of blood, CSF can be distinguished from nasal secretions because the CSF glucose concentration is 30 mg/dL or more, whereas lacrimal secretions and nasal mucus usually contain less than 5 mg/dL.

After determining the patient's level of consciousness (alert, lethargic, stuporous, or comatose), a focused mental status examination should be performed if the patient is conversant. Particular attention should be paid to attention, concentration (counting backward from 20 to 1 or reciting the months in reverse), orientation, and memory, including assessment for retrograde and anterograde amnesia.

Eye movements and pupillary size, shape, and reactivity to light should be noted. A sluggishly reactive or dilated pupil suggests transtentorial herniation with compression of the third nerve. A midposition, poorly reactive, irregular pupil may result from injury to the oculomotor nucleus in the midbrain tegmentum. Nystagmus often follows a concussion. In comatose patients, the oculocephalic and oculo-vestibular reflexes should be tested (see [Chapter 4](#)).

Motor examination should focus on identifying asymmetric weakness or posturing. Spontaneous movements should be assessed for preferential use of the limbs on one side. If the patient is not fully cooperative, lateralized weakness can be detected by an asymmetry in tone or tendon reflexes, or by the presence of an arm drift, preferential localizing response to sternal rub, or extensor plantar reflex. Noxious stimuli, such as pinching the medial arm or applying nailbed pressure, may reveal subtle motor posturing in a limb that otherwise moves normally. *Decorticate posturing* (flexion of arms, extension of legs) results from injury to the corticospinal pathways at the level of the diencephalon or upper midbrain. *Decerebrate posturing* (extension of legs and arms) implies injury to the motor pathways at the level of

the lower midbrain, pons, or medulla.

Gait is particularly important to check in low-risk patients who are treated and released without CT. Balance and equilibrium, tested by tandem heel-to-toe walking, are frequently impaired after a concussion.

Radiography and Imaging

In the United States, CT has become the imaging method of choice for head injury. CT is more informative than plain skull films for detecting skull fractures and provides unsurpassed sensitivity for detecting intracranial blood. MRI is better for detecting subtle injury to the brain, particularly focal lesions related to DAI, but is generally not suitable for emergency evaluations because of the time and expense.

There has been intense debate about guidelines for taking skull films or CT after mild head injury. In 1987, guidelines were published for skull radiography after head injury, but the widespread availability of CT since then has made skull films obsolete, and these criteria have now been adopted for CT. In general, all patients with head injury should have CT, except for those who are low risk—without concussion, with no neurologic abnormalities on examination, and with no evidence or suspicion of a skull fracture, alcohol or drug intoxication, or other moderate-risk criteria ([Table 63.2](#)). The likelihood of detecting intracranial hemorrhage by CT in these patients is only 1 in 10,000.

CTs of head-injured patients should be assessed for the presence of epidural or subdural hematoma, subarachnoid or intraventricular blood, parenchymal contusions and hemorrhages, cerebral edema, and “gliding contusions” related to DAI. With bone-window settings, fractures, sinus opacification, and pneumocephalus can be identified. CT evidence of mass effect and brain tissue displacement—compression or obliteration of the mesencephalic cisterns or midline shift—correlates with increased ICP and decreased chances of survival.

MANAGEMENT

Admission to the Hospital

Low-Risk Group

Low-risk patients, who meet all criteria described in [Table 63.2](#), can generally be discharged from the emergency room without CT, as long as a responsible person is available to observe the patient for the next 24 hours. In general, these are patients who did not sustain a concussion and have normal findings on neurologic examination. Patients are given a checklist of symptoms (e.g., headache, vomiting, confusion) and instructed to return immediately to the emergency room if any occur.

Moderate-Risk Group

Among patients who have experienced a concussion, a normal Glasgow Coma Scale score of 15 (alert, fully oriented, and following commands) and normal CT eliminate the need for hospital admission. These patients can be discharged to home for observation with a warning card, even in the presence of headache, nausea, vomiting, dizziness, or retrograde amnesia, because the risk of a significant intracranial lesion developing thereafter is minimal. Criteria for hospital admission for patients with head injury are listed in [Table 63.6](#).

-
- Intracranial blood or fracture identified on head computed tomography (CT)
 - Confusion, agitation, or depressed level of consciousness
 - Focal neurologic signs or symptoms
 - Posttraumatic seizure
 - Alcohol or drug intoxication
 - Significant comorbid medical illness
 - Lack of a reliable home environment for observation
-

TABLE 63.6. CRITERIA FOR HOSPITAL ADMISSION AFTER HEAD INJURY

Patients with mild-to-moderate neurologic deficits (generally corresponding to Glasgow Coma Scale scores of 9 to 14) and CT findings that do not require neurosurgical intervention should be admitted to an intermediate or intensive care unit (ICU) for observation. A follow-up CT at 24 hours is often helpful to check for progression of bleeding.

High-Risk Group

All patients with a serious head injury are admitted to the hospital. An early neurosurgical consultation is crucial, because once the patient has been stabilized, assessed, and imaged, the immediate consideration is whether an indication exists for emergent surgical intervention. If the decision is made to operate, surgery should proceed immediately, because delays can only increase the likelihood of further brain damage during the waiting period. Medical management of severe injury patients should take place in an ICU. Although little can be done about brain damage that occurs on impact, ICU care can play a major role in reducing secondary brain injury that develops over hours to days.

Surgical Intervention

Simple wounds of the scalp should be thoroughly cleaned and sutured. Compound fractures of the skull should be completely debrided. Operative treatment of compound fractures should be performed as soon as possible but may be delayed for 24 hours until the patient is transported to a hospital equipped for this purpose or until the patient is hemodynamically stable. Elevation of small depressed fractures need not be performed immediately, but the depressed fragments should be elevated before the patient is discharged from the hospital, particularly if the inner table of the skull is involved.

The treatment of acute subdural, epidural, or parenchymal hematoma with mass effect is *craniotomy* and surgical removal of the clot. The bleeding point should be identified and either ligated or clipped. The operative results depend to a great extent on the degree of associated brain damage. In the absence of coexisting brain injury, remarkable improvement can occur after evacuation of a subdural or epidural hematoma, with disappearance of the hemiplegia or other focal neurologic signs.

Burr hole evacuation is insufficient for acute subdural and epidural hematomas, but for liquified chronic subdural hematomas, one or more burr holes can be placed to allow drainage of the collection over several days. A plastic catheter (Jackson-Pratt drain) is usually placed in the subdural space for several days until the drainage subsides.

Intracranial Pressure Management

As a general rule, an ICP monitor should be placed in all head-injured patients who are comatose (Glasgow Coma Scale score 8) after resuscitation, unless the prognosis is sufficiently dismal that aggressive care is unwarranted. Intracranial hypertension occurs in over 50% of comatose patients with CT evidence of mass effect from intracranial hemorrhage or cerebral edema and in 10% to 15% of patients with normal scans. A ventricular catheter or fiberoptic parenchymal monitor may be used. Ventriculostomy has the advantage of allowing CSF drainage to reduce ICP but has a high risk of infection (approximately 15%), which increases sharply if a

catheter is in place for more than 5 days. The risk of infection or hemorrhage is substantially lower with parenchymal ICP monitors (approximately 1% to 2%).

Normal ICP is less than 15 mm Hg, or 20 cm H₂O. Cerebral perfusion pressure (CPP) is routinely monitored in conjunction with ICP because it is an important determinant of cerebral blood flow; CPP is defined as mean arterial blood pressure minus ICP. The goal of ICP management after head injury is to maintain ICP less than 20 mm Hg and CPP greater than 70 mm Hg.

Contemporary ICP management has changed in two important aspects: CPP manipulation has become increasingly emphasized, and the potential for overzealous hyperventilation to aggravate ischemia by causing excessive vasoconstriction has become increasingly appreciated. A stepwise management protocol ([Table 63.7](#)) is followed for treating ICP elevations greater than 20 mm Hg for more than 10 minutes.

1. Consider repeat computed tomography and surgical removal of an intracranial mass lesion or ventricular drainage.
2. I.v. sedation to attain a motionless quiet state.
3. Pressor infusion if CPP <70 mm Hg, or reduction of blood pressure if CPP remains >120mm Hg.
4. Mannitol 0.25–1 g/kg i.v. every 2–6 h as needed.
5. Hyperventilation to Pco₂ levels of 28–32 mm Hg
6. High-dose pentobarbital therapy (load with 5–20 mg/kg, maintain with 1–4 mg/kg/h).
7. Systemic hypothermia.

See text for details.
CPP, cerebral perfusion pressure.
From Mayer SA, Dennis L, 1998.

TABLE 63.7. STEPWISE TREATMENT PROTOCOL FOR ELEVATED ICP (> 20 mm Hg FOR MORE THAN 10 MIN) IN A MONITORED PATIENT

An acute severe increase in ICP always prompts a repeat CT to assess the need for a definitive neurosurgical procedure. If the patient is agitated or “fighting” the ventilator, an intravenous sedative agent such as propofol or fentanyl should be given to attain a quiet motionless state. Thereafter, if CPP is less than 70 mm Hg, vasopressors such as dopamine or phenylephrine can lead to reduction of ICP by decreasing cerebral vasodilation that occurs in response to inadequate perfusion. Alternately, if CPP is more than 120 mm Hg, blood pressure reduction with intravenous labetalol or nicardipine can sometimes lead to a parallel decrease of ICP.

Mannitol and hyperventilation are used only after sedation and CPP management fail to normalize ICP. Mannitol, an osmotic diuretic, lowers ICP via its cerebral dehydrating effects. The initial dose of mannitol 20% solution is 1 to 1.5 g/kg, followed by doses of 0.25 to 1.0 g/kg as needed. Further doses should be given on the basis of ICP measurements rather than on a standing basis. The effect of mannitol is maximal when given rapidly; ICP reduction occurs within 10 to 20 minutes and can last for 2 to 6 hours. Serum osmolality should be monitored closely, with a secondary goal of attaining levels of 300–320 mOsm/kg. Urinary losses should be replaced with normal saline to avoid secondary hypovolemia.

Hyperventilation lowers ICP by inducing cerebral alkalosis and reflex vasoconstriction, with a concomitant reduction of cerebral blood volume. Hyperventilation to Pco₂ levels of 28 to 32 mm Hg can lower ICP within minutes, although the effect gradually diminishes over 1 to 3 hours as acid-base buffering mechanisms correct the alkylsosis within the central nervous system. Overly aggressive hyperventilation to Pco₂ levels less than 25 mm Hg may exacerbate cerebral ischemia and should be avoided.

High-dose barbiturate therapy with pentobarbital, given in doses equivalent to those used for general anesthesia, effectively lowers ICP in most patients who are refractory to the steps outlined above. The effect of pentobarbital is multifactorial but most likely stems from a coupled decrease in cerebral metabolism, blood flow, and blood volume. Pentobarbital can cause profound hypotension and usually requires the use of vasopressors to maintain CPP ≥70 mmHg. Systemic hypothermia (32 to 33°C) is used in some centers to treat increased ICP refractory to pentobarbital, but experience with this technique is limited. The mortality of head-injured patients with increased ICP refractory to pentobarbital exceeds 90%.

Intensive Care Unit Management of Severe Head Injury

Severely head injured patients are best treated in an ICU. In some hospitals, head injuries are treated in a special neurologic or neurosurgical ICU. A time-coded flow sheet is helpful to allow for continuous updating of the patient's clinical, neurologic, and physiologic status.

Serial Neurologic Evaluation

The patient should be examined repeatedly to evaluate level of consciousness and the presence or absence of signs of injury to the brain or cranial nerves. Variations in level of consciousness, reflected by changes in the Glasgow Coma Scale score, or the appearance of hemiplegia or other focal neurologic signs should prompt repeat CT.

Airway and Ventilation

In general, patients who are unable to protect their airway due to depressed level of consciousness should be intubated with an endotracheal tube. Routine hyperventilation is not recommended: in the absence of increased ICP, ventilatory parameters should be set to maintain Pco₂ at 35 to 40 mm Hg and Po₂ at 90 to 100 mm Hg.

Blood Pressure Management

If the patient shows signs of hemodynamic instability, a radial artery catheter should be placed to monitor blood pressure. Because cerebral blood flow autoregulation is frequently impaired in acute head injury, mean blood pressure (or CPP if ICP is being monitored) must be carefully regulated to avoid hypotension, which can lead to cerebral ischemia, or hypertension, which can exacerbate cerebral edema.

Fluid Management

Only *isotonic fluids*, such as 0.9% (normal) saline or lactated Ringer solution, should be administered to head-injured patients, because the extra free water in half-normal saline or D5W can exacerbate cerebral edema. Colloid solutions (5% or 25% albumin) or hypertonic (3% or 9%) saline may also be used in patients with increased ICP, but their benefit remains unclear. Central venous pressure monitoring may be helpful to guide fluid management in hypotensive or hypovolemic patients.

Nutrition

Severe head injury leads to a generalized hypermetabolic and catabolic response, with caloric requirements that are 50% to 100% higher than normal. Enteral feedings via a nasogastric or nasoduodenal tube should be instituted as soon as possible (usually after 24 to 48 hours). Parenteral nutrition carries significant risks (primarily infection and electrolyte derangements) and should be used only if enteral feeding cannot be tolerated.

Sedation

Patients may be agitated or delirious, which can lead to self-injury, removal of monitoring devices, systemic and cerebral hypermetabolism, and increased ICP. Intubated patients can be sedated using a continuous intravenous infusion of a rapidly acting sedative agent such as propofol or fentanyl, which can be turned off

periodically to allow neurologic assessments. Nonintubated patients can be treated with haloperidol 2 to 10 mg intramuscularly every 4 hours as needed.

Temperature Management

Fever (greater than 101°F) exacerbates traumatic and ischemic brain injury and should be aggressively treated with acetaminophen or cooling blankets. A single randomized trial in 82 patients with Glasgow Coma Scale scores of 3 to 7 showed that initial 24-hour management with hypothermia (32 to 33°C) and vecuronium and fentanyl to prevent shivering improved outcome. More studies are under way to determine whether systemic hypothermia should become standard care in comatose patients with traumatic brain injury.

Anticonvulsants

Phenytoin or fosphenytoin (15 to 20 mg/kg loading dose, then 300 mg/day) reduced the frequency of early (i.e., first week) posttraumatic seizures from 14% to 4% in a clinical trial of patients with intracranial hemorrhage but did not prevent later seizures. Carbamazepine or valproic acid are acceptable alternatives. If the patient has not experienced a seizure, prophylactic anticonvulsants should be discontinued after 7 days. Anticonvulsant levels should be monitored closely, because subtherapeutic levels frequently result from drug hypermetabolism.

Nimodipine for Subarachnoid Hemorrhage

In a clinical trial, nimodipine 60 mg orally every 6 hours was associated with improved outcome in head injury patients with evidence of subarachnoid hemorrhage on admission CT. Nimodipine may increase neuronal ischemic tolerance at the cellular level or improve collateral blood flow. Hypotension was the most common adverse event.

Steroids

Glucocorticoids have been used to treat cerebral edema for years, but have not been shown to favorably alter outcome or lower ICP in head-injured patients and may lead to increased risk of infection, hyperglycemia, or other complications. For these reasons, dexamethasone and other steroids are not recommended for use in patients with head injury.

Deep Vein Thrombosis Prophylaxis

Patients with head injury who are immobilized are at high risk for lower extremity deep vein thrombosis and pulmonary thromboembolism. Pneumatic compression boots should be routinely used to protect against this risk, and subcutaneous heparin 5,000 U every 12 hours can be safely added 72 hours after injury, even in the presence of intracranial hemorrhage.

Gastric Stress Ulcer Prophylaxis

Patients on mechanical ventilation or with coagulopathy are at increased risk of gastric stress ulceration and should receive ranitidine 50 mg intravenously every 8 hours, famotidine 20 mg intravenously every 12 hours, or sucralfate 1 g orally every 6 hours.

Antibiotics

The routine use of prophylactic antibiotics in patients with open skull injuries is controversial, and opinions are sharply divided. Prophylactic antibiotics with gram-positive activity, such as oxacillin, are often used to reduce the risk of meningitis in patients with CSF otorrhea, rhinorrhea, or intracranial air; however, these agents may increase the risk of infection with more virulent or resistant organisms.

ACUTE COMPLICATIONS OF HEAD INJURY

Cerebrospinal Fluid Fistula

CSF fistulas result from tearing of the dura and arachnoid membranes. They occur in 3% of patients with closed head injury and in 5% to 10% of those with basilar skull fractures. They are usually associated with fractures of the ethmoid, sphenoid, or orbital plate of the frontal bone.

CSF leakage ceases after head elevation alone for a few days in 85% of cases. If it persists, a lumbar drain may lower CSF pressure, reduce flow through the fistula, and hasten spontaneous closure of the dural tear. Patients with dural leaks are at increased risk for meningitis, and although the use of prophylactic antibiotics is controversial, most physicians use them. Persistent CSF otorrhea or rhinorrhea for more than 2 weeks calls for surgical repair, as does recurrent meningitis. If there is a leak and the site of the fracture is not evident, a metrizamide CT study is the diagnostic method of choice.

Pneumocephalus

Pneumocephalus is a collection of air in the intracranial cavity, usually in the subarachnoid space. It usually occurs with a fracture of a frontal sinus. The air may not appear for several days after injury and then only after the patient sneezes or blows his or her nose. The presence of intracranial air has the same implications as a CSF fistula. Most pneumocephalus are asymptomatic, but headaches or mental symptoms may result from intracranial hypotension. The diagnosis is made by CT, and the site of the dural defect can be identified by CT-metrizamide studies. If spontaneous resorption of the air does not occur, the opening in the frontal sinus should be surgically repaired through a transfrontal craniotomy.

Carotid-Cavernous Fistula

A *carotid-cavernous fistula* is characterized by the clinical triad of pulsating exophthalmos, ocular chemosis, and orbital bruit. They result from traumatic laceration of the internal carotid artery as it passes through the cavernous sinus; approximately 20% of cases are nontraumatic, and most of these are related to spontaneous rupture of an intracavernous internal carotid artery aneurysm. Other symptoms may include distended orbital and periorbital veins and paralysis of the cranial nerves (III, IV, V, and VI) that pass through or within the wall of the cavernous sinus.

Traumatic carotid-cavernous fistulae may develop immediately or days after injury. Angiography is required to confirm the diagnosis ([Fig. 63.8](#)). Endovascular treatment, with a balloon placed through the defect in the arterial wall into the venous side of the fistula, is the most effective means of repair and can prevent permanent visual loss due to venous retinal infarction if performed quickly.

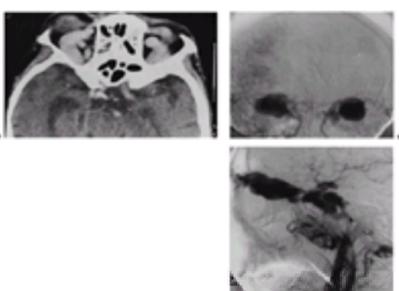

FIG. 63.8. Carotid cavernous fistula. **A:** Axial contrast-enhanced computed tomography demonstrates prominent superior ophthalmic veins bilaterally. Anteroposterior (**B**) and lateral subtraction (**C**) films from a right carotid arteriogram demonstrate bilateral carotid cavernous fistulae with drainage anterior into the superior ophthalmic

veins. (Courtesy of Drs. T.L. Chi, J.A. Bello, and S.K. Hilal.)

Vascular Injury and Thrombosis

Traumatic injuries may be associated with dissections of the extracranial or intracranial internal carotid or vertebral arteries, which can lead to thrombosis at the site of the intimal flap and stroke due to distal thromboembolism. The diagnosis is established by conventional or MR angiography, and anticoagulation should be used to prevent thrombosis and infarction, although this may be relatively contraindicated if there is coexisting intracranial hemorrhage.

Basilar skull fractures are sometimes associated with thrombosis of adjacent dural sinuses. In most cases, *dural sinus thrombosis* takes several days to develop; the sigmoid and transverse sinuses are most commonly involved. Symptoms are related to increased ICP or associated venous infarction and may include headache, vomiting, seizures, depressed level of consciousness, or hemiparesis. The diagnosis is established by angiography or MR venography, and anticoagulation is the treatment of choice (see [Chapter 46](#)).

In patients with large epidural or subdural hematomas and subfalcine herniation, secondary cerebral infarction can sometimes result from compression of the ipsilateral anterior cerebral artery against the falx or contralateral posterior cerebral artery against the tentorium.

Cranial Nerve Injury

Injury to the cranial nerves is a frequent complication of fracture at the base of the skull (see [Chapter 68](#)). The facial nerve is the most commonly injured nerve, complicating 0.3% to 5% of all head injuries. Occasionally, the paralysis may not develop until several days after the injury. Partial or complete recovery of function is the rule with traumatic injuries to the cranial nerves, with the exception of the first or second nerves.

Infections

Infections within the intracranial cavity after injury to the head may be extradural (osteomyelitis), subdural (empyema), subarachnoid (meningitis), or intracerebral (abscess). For more information, refer to [Chapter 21](#).

Extradural infections are usually accompanied by, and are secondary to, infection of the external wound or osteomyelitis of the skull. *Subdural empyema* is a closed-space infection between the dura and arachnoid. *Intracerebral abscess* may follow compound fractures of the skull or penetrating injuries to the brain. All these infections usually develop in the first few weeks after injury but may be delayed. Diagnosis is suggested by CT and MRI and confirmed by culture of the infected tissue. Treatment includes surgical debridement and administration of antibiotics.

Meningitis may follow any type of open fracture associated with tearing of the dura, including compound fractures, penetrating missiles, or linear fractures that extend into the nasal sinuses or the middle ear. Within the past decade, there have been reports of meningitis in as few as 2% and as many as 22% of patients with basilar skull fractures. Meningitis commonly develops 2 to 8 days after injury but may be delayed for several or many months, particularly in patients with fractures through the mastoid or nasal sinuses. Cases that develop within a few days after injury are almost always due to pneumococcus or other gram-positive bacteria, but any pathogenic organism may be the cause. Diagnosis depends on the CSF findings after lumbar puncture. The principles of treatment are those recommended for meningitis in general. The presence of a persistent CSF fistula with rhinorrhea or otorrhea favors the recurrence of meningitis; as many as seven or eight attacks have been reported. Treatment in such cases must include surgical closure of the fistula.

OUTCOME

The outcome that can be expected after head injury is often a matter of great concern, particularly in those with serious injuries. *Depth of coma*, *CT findings*, and *age* are the medical and demographic variables most predictive of late outcome. Other factors of prognostic importance include pupillary responses, hypotension or hypoxemia on admission, and persistently elevated ICP. In the Traumatic Coma Data Bank, an observational study of 746 patients, 33% died, 14% became vegetative, 28% remained dependent with severe disability, 19% regained independence with moderate disability, and only 7% made a full or near-complete recovery.

Severity of coma can be quantified using the admission Glasgow Coma Scale score ([Table 63.3](#)), which has substantial prognostic value: Patients scoring 3 or 4 (deep coma) have an 85% chance of dying or remaining vegetative, whereas these outcomes occur in only 5% to 10% of patients scoring 12 or more. In general, elderly patients do very poorly. In one series of comatose patients older than 65, only 10% survived and only 4% regained functional independence. Death may result from the direct effect of the injury or from the complications that ensue. Attempts to make a firm prognosis in severe head injuries, especially in the early stages, are hazardous because the outcome depends on so many variables. Some indices, however, are valuable as prognostic indicators ([Table 63.4](#)).

Persistent vegetative state is a much-feared potential outcome of traumatic coma. In general, the prospects of recovery from traumatic coma is better than from coma of other causes. Fifty percent of adults and 60% of children who are comatose for 30 days will recover consciousness within 1 year, compared with 15% of patients in coma from nontraumatic causes. Recovery of consciousness is operationally defined as the ability to follow commands convincingly and consistently.

Almost every patient with severe brain injury shows mental changes after recovery of consciousness from prolonged coma; disorientation and agitation are particularly common. With time, there is usually considerable improvement in the signs and symptoms of brain damage, but permanent sequelae are common. In addition to cognitive and motor deficits, headache, dizziness, or vertigo may be present in the immediate posttraumatic period. These symptoms usually disappear in a few weeks but may be prolonged for months.

Disabling cognitive problems include impaired memory, attention, and concentration; slowing of psychomotor speed and mental processing; and changes in personality. There may be loss of memory for the events that preoccurred in the immediate period after recovery of consciousness (*posttraumatic amnesia*) and a similar amnesia for the events immediately preceding the injury (*pretraumatic amnesia*). These periods of amnesia may encompass days, weeks, or years.

Early cognitive, physical, and occupational therapy is an important part of optimizing recovery after traumatic brain injury. Physical therapy, including range of motion exercises to prevent limb contractures, can begin even while patients are still in the ICU. Once the patient is stabilized, they should be transferred to an acute or subacute rehabilitation facility. Whether cognitive rehabilitative measures truly improve neuropsychological outcome remains to be established.

In a study of patients with moderate or severe injuries, only 46% returned to work 2 years later, and most of those who did return to work did not go back to their preinjury positions. Only 18% were financially independent, inducing considerable stress on the family. Vocational training can play a key role in helping patients reintegrate into the workplace.

Postconcussion Syndrome

Approximately 40% of patients who have sustained minor or severe injuries to the head complain of headache, dizziness, fatigue, insomnia, irritability, restlessness, and inability to concentrate. Often, there is overlap with symptoms of anxiety and depression. This group of symptoms, which may be present for only a few weeks or may persist for years, is known as *postconcussion syndrome*.

Postconcussion syndrome is somewhat misleadingly named, because affected individuals need not have suffered loss of consciousness. There are no criteria that make it possible to define the role of either physiologic or psychologic factors in the etiology of postconcussion syndrome. Patients may be severely disabled yet have a normal finding on neurologic examination and no MR evidence of brain injury. The correlation between the severity of the original injury and the severity and duration of later symptoms is poor. For instance, the incidence of postconcussion syndrome is not related to the duration of retrograde amnesia, coma, or the posttraumatic amnesia. In some patients, the symptoms may be related to the brain damage; in others, they seem to be entirely psychogenic. In practice, it is often difficult to sort out the complicated origins of this disorder.

Posttraumatic symptoms may develop in patients who had previously shown normal adjustment but are more likely to occur in patients who had psychiatric symptoms before the injury. Factors such as domestic or financial difficulties, unrewarding occupations, and the desire to obtain compensation, financial or otherwise, tend to produce and may prolong the symptoms once they have developed.

The prognosis of the postconcussion syndrome is uncertain. In general, progressive improvement may be expected. The duration of symptoms is not related to the severity of the injury. In some patients with only a mild injury, symptoms continue for a long period, whereas patients with severe injuries may have only mild or transient symptoms. By and large, however, it is a matter of 2 to 6 months before the headache and dizziness and the more definite mental changes show much improvement. Treatment for postconcussion syndrome is based on psychotherapy, cognitive and occupational therapy, vocational rehabilitation, and treatment with antidepressant or anti-anxiety agents.

Seizures and Posttraumatic Epilepsy

Posttraumatic seizures may be immediate (within 24 hours), early (within the first week), or late (occurring after the first week).

The exact incidence of seizures after head injury is unknown, but figures in the literature vary from 2.5% to 40%. As a rule, the more severe the injury, the greater the likelihood that seizures will develop. The overall incidence of seizures is about 25% in those with brain contusion or hematoma and as high as 50% in those with penetrating head injury.

Immediate seizures are infrequent; they are a risk factor for further early seizures but not for late seizures. Early seizures occur in 3% to 6% of patients with head injury who are admitted to the hospital. Risk factors include depressed skull fracture, penetrating head injury, intracranial hemorrhage (epidural, subdural, or intraparenchymal), prolonged unconsciousness (more than 24 hours), and immediate seizures; the risk of early seizures in a patient with any of these risk factors is 20% to 30%. Children are more likely to develop early posttraumatic seizures than are adults. Patients who experience early seizures remain at risk for late seizures and should be maintained on anticonvulsants after discharge from the hospital.

The overall incidence of late seizures (posttraumatic epilepsy) after closed head injury is 5%, but the risk is as high as 30% among patients with intracranial hemorrhage or a depressed skull fracture and 50% among patients who have experienced early seizures. About 60% of patients experience their initial seizure during the first year, but the risk of seizures remains increased for up to 15 years after a severe head injury. Because 25% of patients have only a single late seizure, many practitioners begin anticonvulsants only after a second seizure occurs. Therapy of posttraumatic epilepsy is discussed in [Chapter 140](#).

Posttraumatic Movement Disorders

Movement disorders are a rare sequelae of head injury. Action tremor is most common, although its pathogenesis remains obscure. Cerebellar ataxia, rubral tremor, and palatal myoclonus have been described in patients with focal shearing injuries of the superior cerebellar peduncle, midbrain, and dentatorubroolivary triangle, respectively. Parkinsonism and other basal ganglia syndromes have been reported after a single episode of head trauma. The treatment of movement disorders is discussed in Section XV.

PEDIATRIC TRAUMA

Injuries are the leading cause of death in children, and brain injury is the most common cause of pediatric traumatic death. Motor vehicle accidents account for the largest number of severe injuries in children, but children are also prone to unique forms of injury, such as birth injury and child abuse. Children are more likely than adults to experience brain swelling and seizures after head injury and in general make better recoveries.

Birth Injuries

The common neurosurgical lesions of neonates are skull fractures; subarachnoid hemorrhage; and epidural, subdural, and intracerebral hematomas. Extracranial subgaleal and subperiosteal hematomas due to trauma at the time of delivery are fairly common and rarely need treatment. Acute subdural hematoma was once considered the most common intracranial birth injury, but this syndrome seems to be disappearing with improved obstetric care. Diagnosis by subdural taps has been supplanted by the use of CT. Surgical evacuation is accomplished through a craniotomy rather than a burr hole.

Leptomeningeal Cysts

A rare complication of head injury is the formation of a leptomeningeal cyst in the space between the pia mater and the arachnoidal membrane. This complication is most common in infants and children less than 2 years of age; the clinical hallmark is a palpable nontender swelling that is getting larger in the area of a previous fracture. Also known as a "growing fracture," leptomeningeal cysts may develop when a linear fracture of the skull is associated with laceration of the dura; pulsation of the brain forces CSF into a cyst formed between the edges of the fracture, producing erosion of the skull. The diagnosis is made from radiographic evidence of a circular or oval area of erosion of the skull in a patient who has had a previous fracture of the skull. Treatment consists of excision of the cyst and repair of the dural defect.

Child Abuse

Child abuse is an important problem encountered in the care of children with head trauma. Certain characteristics may enable the physician to identify an abused child. There is often a delay in seeking medical care, and there may be a history of multiple previous injuries. Details of the history may be sketchy or may be inconsistent with the severity of the child's injury. Examination may reveal bruises or injuries that do not normally result from the day-to-day activities of a child, including injuries between the shoulder blades, circumferentially around the arm, or behind the legs. A skeletal survey may reveal multiple healed fractures.

The "shaken baby syndrome" should be suspected in children with significant neurologic injury with little evidence of external trauma. Retinal hemorrhages occur frequently and may be pathognomonic for this syndrome, and subdural hematoma is also common. MRI can play a pivotal role in the diagnosis by identifying intracranial lesions of varying ages. Established protocols should be followed once there is a suspicion of child abuse to ensure that the child will not be subjected to further injury.

NEUROLOGY OF PROFESSIONAL BOXING

The term "punch drunk" is ascribed to a 1928 paper by Martland; another term is dementia pugilistica. The current nonprejorative term is *chronic traumatic encephalopathy*. Whatever the name, there seems to be little doubt that professional boxers are especially at risk for a syndrome that is dominated by parkinsonism and other extrapyramidal features—tremor, ataxia, cerebellar signs, and, in some, dementia. The disorder is attributed to the cumulative effects of repetitive subconcussive blows to the head. Pathologic studies show hypothalamic abnormalities, degeneration of substantia nigra, widespread neurofibrillary changes, and scarring of cerebellar folia.

Although the syndrome is well known, few prospective studies have been done to determine precise risk factors, whether signs can be seen early enough to prevent the severe late syndrome, whether the syndrome could be prevented by offering protective guidelines for boxing matches (e.g., neurologic examination, including CT and MRI, better head protection, different gloves), and whether it is a progressive disorder after the boxer has ceased to fight. According to the early study of Critchley (1957), manifestations begin from 6 to 40 years after starting a boxing career, with an average of 16 years.

Other sports involve the risk of serious injury, but only boxing includes the goal of deliberately injuring the brain of an opponent. Knockout is the prized achievement. Many neurologists have therefore urged the abolition of boxing, but this has not yet been achieved, and it may never be; many powerful social forces promote the sport in the United States and elsewhere. If boxing is not to be banned, physicians and other health care workers must take every opportunity to regulate the profession. Physicians must stop matches when there is evidence of brain injury. Better protection for boxers must be available during training and in the ring. Appropriate prospective epidemiologic studies are needed. Once the symptoms of chronic traumatic encephalopathy have become evident, no therapy is effective.

[Pathology](#)
[Neurologic Assessment and Classification](#)
[Diagnosis](#)
[Course and Prognosis](#)
[Treatment](#)
[Complications](#)
[Suggested Readings](#)

Trauma to the vertebral column may irreversibly damage the spinal cord and accompanying nerve roots. Spinal cord injury is acute and unexpected, dramatically changing the course of an individual's life. The social and economic consequences to patient, family, and society may be catastrophic.

The annual incidence of spinal cord injury is estimated at 30 to 40 per 1,000,000 persons, with about 8,000 to 10,000 new cases per year. The prevalence is approximately 900 to 950 per 1,000,000, with approximately 250,000 patients now in the United States. The mortality rate is estimated at 48%; approximately 80% of deaths occur at the scene of the accident. After hospital admission, mortality is estimated at 4% to 17%.

The most common level of injury is C-5 followed by C-4 and C-6. The most common lower level is T-12 followed by L-1 and T-10.

ETIOLOGY

Of those suffering spinal cord trauma, 65% are younger than 35 years. The greatest incidence occurs between 20 to 24 years. After age 35, there is a slightly increased incidence of spinal cord injury in those between 55 and 59 years. The male-to-female ratio is at least 3:1 to 4:1. The incidence of injury is highest during the summer months and on weekends.

Road accidents are the most common cause of traumatic paraplegia and tetraplegia. Patients in this group, which encompasses single and multiple motor vehicle accidents, motorcycle accidents, and injuries to pedestrians, account for approximately 48% of all new cases of spinal cord injury. Other causes include falls (21%), sports injuries (hockey, football, diving, and water sports) (13%), industrial accidents (12%), and acts of violence such as stabbing and gunshot wounds (16%). There are regional differences in frequency of injury (i.e., in large cities, gunshot wounds and stabbing are frequent causes). In the elderly, falls are an increasingly common cause of spinal injury. The relative frequency of these causes differs in different societies ([Table 64.1](#)). Birth injuries, particularly in breech deliveries, may result in a stretched or compressed spinal cord due to traction and hyperextension of the cervical spine.

Causes	%
Motor vehicle accidents	51.5
Car, truck	27
Motorcycle	21
Bicycle	3
Pedestrian	1
Domestic and industrial accidents	27
Domestic	16
Falls in house: stairs, ladders, trees	16
Industrial	11
Falls from scaffolds, ladders; crush injuries	11
Athletic injuries	16
Diving in shallow water	7
Rugby	3
Horse riding	1
Gymnastics, skiing, others	5.5
Personal injury	5
Self-harm	4.5
Criminal assault	0.5
Major catastrophe	0.5
Air crash	0.5

TABLE 64.1. CAUSES OF SPINAL CORD INJURY: NEW ADMISSIONS TO DUKE OF CORNWALL SPINAL TREATMENT CENTER 1989–1991

MECHANISM OF INJURY

Indirect severe force applied to the vertebral column is the most frequent mechanism of spinal cord injury. Such a force, generated during sudden flexion, hyperextension, vertebral compression, or rotation of the vertebral column, may result in dislocation of facet joints, fracture of vertebral bodies, misalignment of the vertebral canal, herniation of disc material, and bone splintering. The spinal cord may consequently be contused, stretched, lacerated, or crushed. When there is preexisting cervical spondylosis or spinal stenosis, a trivial injury may cause major neurologic damage, even without fracture or dislocation. With the advent of magnetic resonance imaging (MRI), it is recognized that disc herniation is a more common cause of spinal contusion than was previously appreciated. Both direct and indirect injury to the cord from comminuted bone may occur when bullets and high-velocity missiles are responsible for the injury.

Direct injury to the spinal cord results from stabbing with a sharp object such as a knife. With stabbing, the protection usually afforded by the laminae is bypassed when the sharp object is directed away from the midline in an angular direction.

Appreciation of the mechanism of injury provides insight into the potential stability or instability of spinal injury. Sudden, violent flexion, particularly in the cervical and thoracic regions, may cause anterior compression fractures of vertebral bodies and unilateral or bilateral facet joint dislocation. Rupture of longitudinal or interspinous ligaments may occur. As a result of severe compression injuries, bursting of a vertebral body may occur, with bone splinters and disc material being pushed into the spinal canal. Rotational injuries may result in unilateral fracture–dislocation with variable trauma to the cord. Hyperextension injuries, caused by a fall forward, result in fracture of the posterior elements of the vertebral bodies. Any combination of forces may occur in a single case. It is therefore important to recognize the mechanism of injury in the assessment. This understanding permits assessment not only of the nature, level, and extent of underlying cord injury but also of the stability of the spinal column at the site of injury.

In summary, an appreciation of the biomechanics of an injury is based on the most prominently recognized applied force. The common mechanisms include flexion, extension, axial compression, or any combination of these forces.

PATHOLOGY

The type and severity of spinal column injury determine the nature and extent of the underlying cord damage. There may be extensive contusion and compression of the cord with partial or complete laceration and gross spinal cord injury. With stab wounds, the pathology may be a discrete hemisection of the cord.

The extent of spinal cord injury results from a direct mechanical blow causing cord disruption of varying degree. This is acute and immediate. Macroscopic examination in acute spinal cord injury reveals a swollen, reddish, soft, and mushy cord. Contusion, extradural hemorrhages of modest size, subdural hemorrhages, and subarachnoid hemorrhage may be seen. Complete transection is rare.

Hyperemia is obvious within 12 to 24 hours. The vascular changes are likely due to the presence of vasoactive agents triggered by prostaglandins and catecholamines. Cross-sections of the swollen cord reveal centrally placed hemorrhages, softening, or necrosis. Microscopic investigation reveals fragmented myelin sheaths, splayed myelin lamellae, broken axons, and eosinophilic neurons. The exudate consists of red cells, polymorphonuclear leukocytes, lymphocytes, and plasma cells. These changes extend several segments above and below the level of injury. The edema and acute reaction subside within several weeks; hemorrhages are absorbed, and the acute exudate is replaced by macrophages, with the most prominent cell being a lipid phagocyte. This reparative stage may

persist for 2 years, resulting in cavitation, gliosis, and fibrosis. In 5 years or more postinjury, the damaged area shrinks, and the cord is replaced by fibrous tissue. There is progressive proliferation of acellular connective tissue, resulting in dense and chronic adhesive arachnoiditis. The chronic results of spinal cord injury may include traumatic neuroma from injured nerve roots, posttraumatic syringomyelia, or spinal stenosis secondary to disc protrusion and associated osteophyte formation.

In traumatic hematomyelia, hemorrhage occurs within the central gray matter. It is limited in extent and is eventually absorbed, leaving a centrally placed, smooth-walled cyst. This differs from the much more common central hemorrhagic softening and necrosis that occur.

On rare occasions, after several years of neurologic stability, residual intramedullary cysts may become distended, leading to a progressive neurologic deterioration. There is no explanation for this delayed myelopathy, referred to as traumatic syringomyelia. The neurologic deterioration that occurs is invariably rostral to the original injury. Traumatic syringomyelia most frequently occurs in the cervical region.

NEUROLOGIC ASSESSMENT AND CLASSIFICATION

A comprehensive, thorough neurologic assessment is pivotal in determining the level, type, and severity of cord injury. Many attempts have been made over the years to standardize the clinical neurologic assessment. A standard assessment would permit comparison of different observations in different centers. One of the original scales was that of Frankel, a global scale devised in 1969; it consists of five groups: (1) no motor or sensory function, (2) no motor but some sensory preservation, (3) useless motor function preserved, (4) useful motor function preserved, and (5) normal function with or without minor neurologic deficit.

The American Spinal Injury Association (ASIA) and the International Medical Society of Paraplegia (IMSOP) jointly published the "International Standards for Neurological and Functional Classification of Spinal Cord Injury" (Maynard et al., 1997). This is an excellent method of clinical neurologic assessment, allowing comparison of findings from center to center and investigator to investigator (Fig. 64.1). The ASIA/IMSOP have also published a new impairment scale that improves on the Frankel scale. This ASIA/IMSOP scale has reduced the number of criteria for the category of incomplete cord transection.

FIG. 64.1. ASIA neurologic examination form for spinal cord injury.

The ASIA/IMSOP impairment scale consists of the following categories:

Complete: no motor or sensory function is preserved in the sacral segments S4 and S5.

Incomplete: sensory but not motor function is preserved below the neurologic level and extends through to the sacral segments S4 and S5.

Incomplete: motor function is preserved below the neurologic level, and the majority of key muscles below the neurologic level have a muscle grade less than 3.

Incomplete: motor function is preserved below the neurologic level, and the majority of key muscles have a muscle grade of 3 or greater.

The following definitions are noted:

Incomplete spinal cord injury: if partial preservation of sensory and/or motor functions is found below the neurologic level and includes the lowest sacral segment, the injury is defined as incomplete. Sacral sensation also includes deep anal sensation. Voluntary contraction of the anal sphincter muscle is used to demonstrate preserved muscle function.

Complete spinal cord injury: this term is used when there is no sensory or motor function in the lowest sacral segment. The neurologic level is given as the lowest level where there is still some evidence of muscle function or sensation but no preservation in the sacral area.

The clinical patterns seen in spinal injury are the following:

- Cauda equina lesions
- Conus medullaris lesions
- Mixed cauda-conus lesions
- Spinal cord injuries
 - Spinal cord concussion
 - Spinal shock
 - Complete cord transection
 - Incomplete cord transection
- Brown-Séquard syndrome
- Central cervical cord syndrome
- Anterior cord syndrome
- Posterior cord syndrome

Damage to the roots of the cauda equina causes flaccid, areflexic paralysis and sensory loss in the area supplied by the affected roots, with paralysis of bladder and rectum. The findings may be symmetric or asymmetric. If only the conus is damaged, there is urinary and fecal incontinence, failure of erection and ejaculation in men, paralysis of the pelvic floor muscles, and sensory impairment, which is frequently dissociated in the saddle region. In a pure conus lesion, tendon reflexes are frequently preserved, but occasionally the ankle jerks are lost. A mixture of anatomically appropriate clinical signs is seen because conus and cauda injuries commonly occur together.

Spinal cord concussion is the term for transient neurologic symptoms with recovery in minutes or hours. Symptoms develop below the level of the blow. *Spinal shock* occurs after an abrupt, complete, or incomplete lesion of the spinal cord. There is immediate complete paralysis and anesthesia below the lesion with hypotonia and areflexia. The plantar responses may be absent, extensor, or equivocal. The areflexic hypotonic state is gradually replaced by pyramidal signs, usually within 3 or 4 weeks. The evolution from an areflexic to hyperreflexic state may be delayed by urinary tract infection, infected bed sores, anemia, or malnutrition.

Chronic and complete transection of the cord after the period of spinal shock results in permanent motor, sensory, and autonomic paralysis below the level of the lesion. Chronic and incomplete transverse section results in different clinical pictures, depending on the pathways involved. In the *Brown-Séquard syndrome* after hemisection of the spinal cord, the following signs are found, usually with the upper level one or two segments below that of the lesion: ipsilateral paresis, ipsilateral corticospinal signs, contralateral loss of pain and temperature sensation, and ipsilateral impairment of vibration and joint position sense. There is usually little loss of

tactile sensation. There may be ipsilateral segmental loss of sensation or weakness appropriate to the level of the lesion.

The *central cervical cord syndrome* is characterized by weakness that is more marked in the arms than the legs, urinary retention, and patchy sensory loss below the level of the lesion. The arms or hands may be paralyzed or moderately weak; in the legs there may be severe paresis or only minimal weakness, with overactive tendon reflexes and Babinski signs. Micturition may be normal. Complete cord transection may be diagnosed at first because there seems to be no cord function below the level of the lesion. Careful testing, however, may reveal sacral sparing and therefore an incomplete lesion. If so, the potential for recovery without operative intervention is better and depends on the degree of central hemorrhage.

In the *anterior cervical cord syndrome*, immediate complete paralysis is associated with mild to moderate impairment of pinprick response and light touch below the injury with preservation of position and vibration sense. This syndrome may be caused by an acutely ruptured disc with or without fracture or fracture–dislocation in the cervical region.

The *posterior cord syndrome* is characterized by pain and paresthesia in the neck, upper arms, and trunk. Paresthesia is usually symmetric and has a burning quality. The sensory manifestations may be combined with mild paresis of the arms and hands, but the long tracts are only slightly affected. The symptoms of both the anterior and posterior cord syndromes are reversible.

Clear demarcation between incomplete and complete spinal cord syndromes may be clinically difficult at the time of injury. An accurate neurologic examination may be feasible only 24 to 48 hours after the injury. This period permits any interference from alcohol, drugs, or multiple trauma to be dealt with, resulting in a more alert and cooperative patient.

DIAGNOSIS

After clinical neurologic assessment and stabilization, diagnosis of the injury is enhanced by diagnostic imaging and neurophysiologic studies. It is essential to obtain accurate and complete plain radiographs of the spinal column at the time of injury. This is done to rule out unsuspected other spinal column pathology.

Anteroposterior (AP) and lateral plain-film x-rays must be taken at the appropriate level as directed by the clinical evaluation. Some observers advise AP and lateral films of the entire spine to rule out clinically unsuspected lesions. Lateral x-rays of the cervical spine encompassing the lower cervical region are mandatory. Open-mouth odontoid views should form part of the initial examination. In thoracic and lumbar injuries, AP, lateral, oblique, and extension views may be required.

Computed tomography (CT) is the best procedure for evaluating uncertain findings on plain x-rays, as well as detecting bone pathology. High-resolution CT with sagittal reconstruction enhances radiologic diagnosis to 95%.

In general, magnetic resonance imaging (MRI) is the best technique for soft tissue imaging and CT is best for detecting bone pathology. Recent advances in MRI technology have overcome technical problems such as slow scanning speed and poor resolution, improving the MR images. Multiplanar high-resolution MRI with T1-weighted and gradient-echo or T2-weighted imaging is the most specific and sensitive technique for soft tissue paraspinal lesions, disc herniation, spinal cord hemorrhage, spinal cord edema, and intra- and extradural hemorrhage. Monitoring of severely injured patients during MRI procedures, although improved, is still inadequate in many institutions. The ability to monitor the critically injured must be a priority when MRI is considered. If MRI is not available, intrathecally enhanced CT is the current best alternative. Standard myelography is seldom done under acute circumstances.

Neurophysiologic assessment of spinal cord function is feasible with the use of sensory and motor evoked responses. Mixed nerve evoked potentials may be useful in determining the integrity of certain spinal cord pathways (e.g., dorsal columns). These procedures are used at times in intensive care units or intraoperatively for monitoring spinal cord function and identifying spinal conduction block.

COURSE AND PROGNOSIS

It is estimated that 48% of patients with a spinal cord injury die within 24 hours of sustaining the injury, the majority at the site of the accident or on arrival at the hospital. Long-term survival depends on the level and extent of the lesion, patient age, and the availability of special treatment units in which multidisciplinary personnel are available.

A long-term follow-up of survival in 1,501 patients with spinal cord injury was presented by a Toronto group in a series of reports (Geisler & Jousse, 1992). The follow-up extended from January 1, 1945, to December 31, 1980, and revealed the following:

1. Spinal cord injured patients had a higher mortality rate than those in the general population.
2. The mortality rate was highest for those with complete lesions, particularly tetraplegia.
3. The mortality rate was significantly reduced over the length of the follow up, especially in complete lesions.
4. The mortality rate of incomplete lesions was closer to that of the general population.
5. There was a marked decrease in the number of deaths caused by renal disease in those with spinal cord injury.
6. Deaths from suicide remained high.

De Vivo and colleagues (1987) studied the 7-year survival following spinal cord injury. This was a retrospective study of 5,131 persons with acute spinal cord injury between 1973 and 1980. All study subjects were treated in one of seven federally designated "model regional spinal cord injury care systems." Each had survived at least 24 hours after injury. The older group fared less well than the younger. Complete lesions predictably did less well than incomplete lesions. The cumulative 7-year survival rate among neurologically complete quadriplegics who were at least 50 years old when injured was only 22.7%. The cumulative 7-year survival rate for all groups was 86.7%.

De Vivo and associates (1990) also studied the influence of age at the time of spinal cord injury on the course of rehabilitation. Data were collected from 866 patients admitted between 1973 and 1985. Compared with patients 16 to 30 years old, patients who were at least 61 years old were (1) 2.1 times more likely to have developed pneumonia, (2) 2.7 times more likely to experience a gastrointestinal hemorrhage, (3) 5.6 times more likely to develop pulmonary emboli, (4) 16.8 times more likely to have renal stones, (5) 3.9 times more likely to have been readmitted to the hospital during the second postinjury year, (6) 2.1 times more likely to have required artificial ventilatory support before discharge, (7) 22.7 times more likely to have been discharged to a nursing home, (8) 71.8 times more likely to be in a nursing home 2 years after injury, and (9) 7.3 times more likely to have used hired attendants during the second postinjury year. Two-year survival rates were 59% for patients ages 61 to 86 years and 95% for those 16 to 30 years. The leading causes of death in patients with spinal cord injury were pneumonia, unintentional injuries, and suicide. Pneumonia was the leading cause of death among tetraplegics in individuals at least 55 years old. In paraplegics and persons younger than 55 years, unintentional injuries and suicides were the leading causes of death.

The prognosis for neurologic recovery is assessed by changes in the ASIA impairment scale grade and by a change in spinal cord level. Recovery of neurologic function depends on the nature and severity of the original injury, associated injuries, age, general health, emergency treatment, appropriate surgery, and complications. Knowledge of the site and severity of the injury and the degree of loss of neurologic function are critical in predicting the recovery of function. It is important to differentiate between neurologic recovery and functional recovery.

On review of a number of studies, certain observations become apparent:

1. Complete loss of cord function below the level of the injury is seen in the largest number of spinal cord injuries.
2. Patients with the most severe injuries have the worst prognosis for any neurologic recovery, as well as the longest hospital stays, the highest mortality, and the most complications.
3. The majority of patients with complete lesions do not show improvement from a functional point of view.

Any recovery after an apparent complete transection is rare. It may be the result of an inappropriate assessment at the time of injury. Incomplete lesions of the spinal cord (anterior, central, Brown-Séquard, and concussion of the spinal cord) carry a better prognosis in terms of return of function.

Recovery rates related to operative or nonoperative care indicate no significant difference in neurologic outcome between the two groups. Dolan and colleagues (1980) detected a decrease in mortality in the surgical group (6.1%) compared to nonsurgical patients (15.2%). The difference in mortality rates may indicate that nonsurgical patients were significantly sicker than operative patients. The value of surgical decompression immediately after injury was studied. Their analysis failed to find any correlation between the outcome and the amount of vertebral body displacement or timing of surgical intervention.

In summary, neurologic assessment within the first 24 to 48 hours after spinal cord injury offers the best method of predicting the eventual outcome. The initial assessment must be done in an alert, cooperative patient, without alcohol or drugs interfering with the assessment. In both complete and incomplete lesions, predictors for return of neurologic function are inconsistent. A serious sign is failure of return of any function within 48 hours of the accident.

TREATMENT

Treatment of the spinal-cord-injured patient encompasses five phases: (1) emergency treatment with attention to circulation, breathing, patent airway, appropriate immobilization of the spine, and transfer to a specialized center; (2) treatment of general medical problems (e.g., hypotension, hypoxia, poikilothermy, ileus); (3) spinal alignment; (4) surgical decompression of the spinal cord, if indicated; and (5) a well structured rehabilitation program.

Prehospital management is critical in preventing further complications. Treatment at the site cannot change the primary spinal cord injury, but it does have a significant effect on preventing secondary damage. Secondary injury of the spinal cord may result from hypotension, hypoxia, lack of immobilization of the spine, poor methods of extrication, inexact monitoring of the patient in transit to hospital, and inability to communicate with the physicians at the accepting trauma center.

Cervical traction must be delayed until adequate radiologic studies can be done.

At the trauma center, the ABC's are reviewed: airway, breathing, and circulation. In addition, D and E have been added, representing "disability" and "exposure." Disability refers to the assessment of neurologic status, and exposure indicates that removal of all clothing is necessary for a complete examination. Clinical signs of shock require the insertion of an arterial line and a Swan-Ganz catheter. Meticulous attention must be paid to cardiac output and mean blood pressure to prevent the cardiopulmonary complications that frequently accompany cord injuries.

Because cord injury may result in loss of sympathetic tone with peripheral vasodilation, bradycardia, and hypotension, secondary ischemic damage may aggravate the spinal cord injury resulting from mechanical causes. Treatment of this potential hazard includes judicious administration of intravenous fluids to prevent fluid overload, alpha-agonists, and, occasionally, intravenous atropine sulfate to counter unopposed parasympathetic activity. Vasomotor paralysis may also cause loss of thermal control and lead to poikilothermy, which can usually be treated by the appropriate use of blankets.

Extrication of the patient from an automobile must be attempted only after the patient's head and back have been strapped in a neutral position on a firm base. There must be similar concern for head and neck stability in diving accidents. Rapid evacuation to a hospital is essential. It is estimated that 10% of patients suffer progressive cord or root damage between the time of diagnosis at the site of the accident and the beginning of appropriate treatment by trained personnel in the hospital.

In the acute phase, intermittent bladder catheterization must be instituted to prevent permanent bladder atony that may result from urinary retention. The insertion of a nasogastric tube will control abdominal distention, reducing the risk of secondary respiratory impairment.

In the acute phase and before imaging, methylprednisolone therapy is indicated. The National Acute Spinal Cord Injury Study demonstrated the benefit of high-dose methylprednisolone in reducing the severity of neurologic damage (Bracken and Holford, 1993). Methylprednisolone is thought to improve spinal cord function by inhibiting lipid peroxidase. Other pharmacologic agents being studied include a 21-aminosteroid, a synthetic nonglucocorticoid steroid that acts as an antioxidant. Gangliosides (acidic glycosphingolipids) are also being evaluated. These agents are thought to become part of the lipid bilayer of the plasma membrane and simulate formation of endogenous gangliosides. GM₁ gangliosides are started within 72 hours of injury and continued for 18 to 32 doses over 3 to 4 weeks. Combination therapy of methylprednisolone followed by gangliosides is being tested. Methylprednisolone is administered by bolus injection of 30 mg/kg followed by 5.4 mg/kg per hour for 23 hours. Benefit was found for both complete and incomplete lesions. Medical complications and mortality rates were unchanged. This treatment must be started within 8 hours of the injury.

With control of systemic functions, attention is directed toward correcting malalignment or instability of the vertebral column. In cervical fracture–dislocation, this is usually done by external skeletal traction (e.g., with Crutchfield tongs, Gardner-Wells tongs, or halo fixation). Thoracolumbar injuries do not lend themselves to external traction, and accordingly surgical stabilization is attempted with devices such as Harrington rods or Weiss springs.

Formerly, it was customary to operate on most patients with acute spinal cord injury to decompress the damaged cord. It has become apparent that surgery has little effect on the neurologic outcome. When cord compression is certain or the neurologic disorder progresses, benefit may be seen following immediate decompression (1 to 2 hours). (Comprehensive reviews of this controversial topic are given in the suggested readings.) There are no set rules for early or late surgical intervention. Clinical judgment and experience direct the appropriate surgical timing in each case.

Patients with spinal cord injury need the facilities of a special spinal care unit. After the acute treatment phase, specialized and continuing therapy is required. Mechanical devices for turning patients are unnecessary; when skilled nursing is available, regular hospital beds may be used. Frequent turning of patients and the use of pillows or pads prevent pressure sores. Antiembolic stockings reduce the incidence of venous thrombosis, and administration of low-dose heparin reduces the risk of pulmonary embolus. Intermittent catheterization of the bladder has replaced use of an indwelling catheter and suprapubic cystostomy. Rehabilitation therapy should be started as soon as possible.

COMPLICATIONS

Bladder

Restoration of a balanced bladder implies a balance between storage and evacuation of urine. A balanced bladder shows no outlet obstruction, a sterile urine, low residual volume (less than 100 mL), and low voiding pressures. Failure to attain this requires further urodynamic studies to determine whether the problem is an obstruction (i.e., bladder neck hypertrophy, prostatism, sphincter-detrusor dyssynergia) or a disturbance of storage (i.e., uninhibited bladder contractions, outflow incontinence, decreased outlet resistance). Intermittent catheterization (no-touch technique) is superior to the use of indwelling catheters in reducing complications and developing bladder training.

Urinary tract complications are the result of high residual urine volume and infection. Cystitis and pyelitis respond to antibiotics. Complications occurring months or years after injury include renal and bladder stones, hydronephrosis, pyonephrosis, bladder diverticula, and ureteral reflux. The incidence of these complications has been markedly reduced in the past few decades.

Bowel Training

For several weeks after acute spinal injury, laxatives and digital removal of feces are necessary. Glycerin suppositories are useful at this time. Stretching of the anus must be avoided. Subsequent training for regular defecation includes the use of laxatives on alternate days and the judicious use of glycerin suppositories, which are inserted approximately 20 minutes before the desired time of evacuation. The goal is a consistent schedule of bowel evacuation.

Pressure Sores

Decubitus ulcers develop in almost all patients with complete transection unless preventive measures are vigorously pursued. These ulcers develop wherever bony prominences are covered by skin; the sacrum, trochanters, heels, ischium, knees, and anterosuperior iliac spine are the most common sites. Preventive measures include eliminating pressure points by padding, frequent changing of patient position, and keeping the bed scrupulously clean. Sheepskin, alternating pressure mattresses, gel pads, and waterbeds are also commonly used for prevention. Mechanical aids (e.g., Foster or Stryker frame or Circolelectric beds) are rarely necessary.

in well organized and well staffed nursing units.

Once pressure sores have developed, repeated changes of dressings, topical agents, and systemic antibiotics may be used, but these are not always successful. The most effective treatment is repositioning the patient so that pressure is continuously removed. Conservative therapy may be beneficial, but surgical debridement and early closure are usually required.

Nutritional Deficiency

Attention to general nutrition is paramount in the treatment of patients with spinal cord injury. Early loss of weight occurs in many patients because of anorexia. In addition, protein may be lost through bedsores. A diet high in protein, calories, and vitamins is advised. If the patient cannot eat sufficient quantities by mouth, parenteral hyperalimentation may be recommended. Anemia may be treated with iron and, when severe, by blood transfusion.

Muscle Spasms

Flexor or extensor spasms require treatment when they are painful, interfere with rehabilitation, or delay healing of bedsores. The aims are reduction in the number of painful and disabling flexor spasms and a decrease in muscle tone when it interferes with function, nursing care, or rehabilitation. The most useful drugs are dantrolene sodium (Dantrium), diazepam, and baclofen (Lioresal). Intrathecal administration of baclofen has become increasingly popular. It is most effective in relieving flexor spasms, may relieve other adverse effects of spasticity and hypertonia, and can be given safely with appropriate precautions. Physical therapy for leg spasticity includes longitudinal myelotomy and percutaneous radiofrequency rhizotomies of the lower lumbar and upper sacral roots. Obturator neurectomy in the pelvis, myotomy of the iliopsoas at the hip, lengthening of the hamstring at the knee, and percutaneous heel cord lengthening are peripheral methods that are safe but have not been carefully evaluated. Intrathecal injections of phenol or absolute alcohol should be used only by those experienced in the treatment of spinal cord injuries.

Sexual Function

Various forms of treatment are available for neurogenic erectile dysfunction. These include a vacuum device that fits over the penis and is kept in place by a constricting ring around the base of the penis; injection of vasoactive agents such as phentolamine mesylate (Regitine), papaverine, or prostaglandin E₁ into the corpora cavernosa; and use of an implantable prosthesis. Sildenafil (Viagra) has been reported to be useful in erectile dysfunction secondary to traumatic spinal cord disease.

Pain

Pain may affect anesthetic areas after complete transverse lesions. There may be sharp shooting pains in the distribution of one or more roots; burning pain may be poorly localized; or deep pain may be localized in the viscera. Treatment includes placebos, spinal anesthesia, posterior rhizotomy, sympathectomy, cordotomy, and posterior column tractotomy. None has been uniformly successful. Narcotic analgesic medication should be avoided, and analgesics generally should not routinely be prescribed. Transcutaneous electrical neurostimulation has been reported to be effective.

Rehabilitation

The ultimate aim for all patients with spinal cord injury is ambulation and economic independence. This can be accomplished in many patients who have injuries below the cervical area and is best done in a rehabilitation center with trained personnel and adequate equipment. Diligent cooperation of the patient with the physiatrist and the application of supportive braces are of major importance. When the arms are paralyzed, the therapeutic goal is more limited, but devices controlled by intact muscles and appropriate surgery may permit useful motion of paralyzed arms. Implantation of diaphragmatic stimulators has permitted survival of high-level-cervical-cord-injured patients.

The development of spinal cord units specializing in the care of tetraplegia and paraplegia is important. An increase in life expectancy, reduction in the frequency of complications, elevation of patient morale, and development of new techniques are some of the benefits.

Finally, the best mode of treatment must be prevention. Nationwide educational programs should be concerned with motor vehicle and water safety, speed limits should be lowered, and the use of seatbelts should be mandatory to reduce the incidence of these injuries.

CHAPTER 65. INTERVERTEBRAL DISCS AND RADICULOPATHY

PAUL C. MCCORMICK

- [Pathogenesis](#)
- [Incidence](#)
- [Lumbar Intervertebral Disc Rupture](#)
- [Thoracic Intervertebral Disc Rupture](#)
- [Cervical Disc Disease](#)
- [Other Diagnostic Features](#)
- [Treatment](#)
- [Suggested Readings](#)

Rupture of an intervertebral disc into the body of a vertebra was first described by Schmorl in 1927. Earlier, in a 1909 text on neurologic surgery, Krause described operating on an iceman who had been diagnosed by Oppenheimer as suffering from a lesion localized to L-4. Krause found an extradural mass that was described pathologically as a chondroma; the operation apparently effected a cure. There were other reports of “chondromas” removed at explorations of the intervertebral area. It remained for Mixter and Barr in 1934 to point out that these lesions were actually fragments of intervertebral discs and that they were responsible for sciatica.

PATHOGENESIS

Displaced disc material may create signs and symptoms by bulging or protruding beneath an attenuated annulus fibrosus, or the material may extrude through a tear in the annulus and project directly into the spinal canal. In either case, the encroaching disc material may irritate or compress nerve roots that are coursing to foramina of exit. In the cervical or thoracic regions, the problem is more complex neurologically because the spinal cord itself, as well as the adjacent nerve roots, may be involved. There, signs and symptoms are caused by either cord compression or a combination of cord and root compression. In the lumbar region, signs and symptoms relate to an individual root lesion (compressed laterally) or to compression of the cauda equina if the disc is large enough to crowd the entire spinal canal.

In the cervical region, the levels most commonly affected are in the C-5 to C-7 segments ([Table 65.1](#)). In the lumbar, area most disc protrusions occur at L4-5 and L5-S1. This pattern suggests that the dynamics of pathologic change are partly related to the trauma of motion and wear and tear. Thoracic disc protrusion, except at the lower thoracic levels, differs from cervical and lumbar disorders in genesis and histopathology. Motion plays no role there because the thoracic vertebrae are designed for stability rather than motion, and the heavy rib cage contributes to the rigidity of this structure. One must therefore look elsewhere for the cause of thoracic disc rupture. On gross and microscopic examination, the lesion is unique, markedly degenerated, and characterized by gritty calcified deposits; it almost never has the consistency of cervical and lumbar ruptured discs; thoracic disc protrusion is more granular and yellowish.

Disc space	L4-5	L5-S1	C5-6	C6-7	C7-T1
Root affected	L4	L5	S1	S1	S1
Muscle affected	Quadriceps	Peroneal, anterior tibial, extensor hallucis longus	Gluteus maximus, gastrocnemius, plantar flexors of toes	Deltoïd, biceps	Triceps, wrist extensors, brachioradial muscle
Area of pain and sensory loss	Anterior thigh, medial shin	Great toe, dorsum of foot	Lateral foot, small toe	Shoulder, anterior arm, radial forearm	Throat, middle fingers
Reflex affected	Knee jerk	Posterior tibial	Ankle jerk	Biceps	Triceps
Straight leg raising	May not increase pain	Aggravates root pain	Aggravates root pain	--	--

TABLE 65.1. COMMON ROOT SYNDROMES OF INTERVERTEBRAL DISC DISEASE

Although trauma has been accepted as the prime cause of disc herniation, it is not the only cause. There seems to be a genetic predisposition in many patients. Trauma may aggravate this propensity and ultimately cause rupture. In the most florid preordained syndrome, there may be multiple levels of severe disc degeneration throughout the spine with progressive clinical involvement in different areas. This syndrome may explain why fusion often fails to prevent recurrent symptoms.

Spinal stenosis, which is an abnormally narrow spinal canal, is an example of an inherited anomaly, as are the spinal abnormalities of achondroplastic dwarfism. These abnormal spinal configurations, along with spondylosis, are major contributors to compression syndromes of the spinal cord and cauda equina. When disc protrusion occurs in a patient with spinal stenosis, it further compromises an already limited canal, as do changes caused by arthritic proliferation or ligamentous degeneration.

The signs and symptoms of herniated discs relate not only to the size and strategic location of the disc fragments but also to the size and configuration of the canal. The anteroposterior and lateral dimensions of the canal, particularly the foramina, play a key role. Spinal stenosis and osteoarthritic changes may compress roots, even with small protrusions. In a canal of normal dimensions, the severity of compression depends more on the site of rupture and the volume of the extruded material. There may be single-root compression or cauda equina compression. A laterally placed lesion in the cervical region may involve a single root, but if it is large enough, it may compress the cord. This is also true in the thoracic region. Although single-root syndromes in the lumbar region are usual, truly ventral or large lesions can lead to less easily recognized clinical pictures. For instance, scoliosis may be the major feature, with severe back pain and muscle splinting but without signs of mechanical root compression in the straight leg-raising test.

INCIDENCE

Rupture of an intervertebral disc is common, especially in the fourth to sixth decades of life. It is rare before age 25 years and uncommon after age 60. About 80% of patients are men. Many patients have a history of earlier trauma.

LUMBAR INTERVERTEBRAL DISC RUPTURE

Root syndromes of intervertebral disc disease are often episodic, so that remissions are characteristic. Pain may be aggravated by Valsalva maneuvers (coughing, sneezing, or straining at defecation). The pain may be restricted to the back or follow a radicular distribution in one or both legs. Lumbar pain may increase after heavy lifting or twisting of the spine. No matter how severe the pain is when the patient is erect, characteristically it is promptly relieved when the patient lies down. Some patients, however, are more comfortable sitting, and some can find no comfortable position. Relief of pain on bedrest is useful in diagnosing disc disease from intraspinal tumor, in which pain is often not relieved or may be worsened.

Examination reveals loss of lumbar lordosis or flattening of the lumbar spine, with splinting and asymmetric prominence of the long erector muscles. A list or tilt may be present, with one iliac crest elevated. This asymmetry is responsible for the commonly diagnosed “longer leg on one side” and the erroneous assignment of the back pain to asymmetry of leg length. (This asymmetry often causes a patient to raise the heel on the shoe of the “short” leg to level of the pelvis.) Range of motion of the lumbar spine is reduced by the protective splinting of paraspinal muscles, and attempted movement in some planes induces severe back pain. There may be tenderness of the adjacent vertebrae. When the patient is erect, one gluteal fold may hang down and show added skin creases because the gluteus is wasted, evidence of involvement of the S-1 root. Passive straight leg raising is reduced in range and increases back and leg pain. Muscle atrophy and weakness or sciatic tenderness and discomfort may occur on direct pressure at some point along the nerve from the sciatic notch to the calf. This is particularly true in older patients.

Paresthesia in the realm of the involved root is common; fasciculation is rare.

The typical syndromes of root compression at lumbar levels are given in [Table 65.2](#), although the signs may not be as distinct in actual practice as the table implies. More than 80% of syndromes affect L-5 or S-1 ([Fig. 65.1](#) and [Fig. 65.2](#)). When the lesion affects L-4 or higher roots, straight leg raising does not stretch the roots above L-5. The affected roots may be tensed, however, by extension of the limb with the knee flexed when the patient is prone, thus reproducing the typical radicular spread of pain.

Disc Space	L2-3	L3-4	L4-5	L5-S1
Patients (n)	1	9	45	42
Weak muscles				
Anterior tibial, extensor hallucis	0	3	13	3
Gastrocnemius, plantar responses of foot	0	0	2	3
Quadriceps	0	3	0	0
